Staying on the Dole

Holger Strulik*, Jean-Robert Tyran** and Paolo Vanini†

This Version: September 2007

Abstract. We develop a simple model of labor market participation, human capital degradation, and retraining. We focus on how non-participation, as a distinct state from unemployment and employment, is determined by the welfare system in interaction with labor market conditions and personal characteristics. We provide a tractable framework to analyze how the decisions to exit the labor force and to mitigate human capital degradation by re-training depend on a broad range of factors such as education, skill degradation, age, labor market shocks, labor taxes, unemployment insurance benefits and social assistance. We extend our framework by allowing for time-inconsistent choices and demonstrate the possibility of an unemployment trap.

Keywords: Unemployment, Non-Participation, Skill Degradation, Retraining, Unemployment Benefits, Social Assistance, Present-Biased Preferences.

1. Introduction

Why do people drop out of the labor force and eventually become inactive? The economists answer is disarmingly simple: Because the incentives are stacked against work. These incentives are importantly shaped by the generosity of the welfare state and by labor market prospects. But the extent to which a particular individual responds to these incentives depends on the characteristics of the person and on labor market prospects. For example, older workers with low productivity will respond differently to changes in the generosity of welfare benefits than younger and highly qualified people, and both groups may respond differently in a boom than if a recession is imminent.

This paper provides a tractable model of non-participation in the labor market. The main focus is to analyze how key parameters of the welfare state (i.e. labor market taxes, the duration and generosity of unemployment benefits and social assistance or welfare in American diction) provide incentives to stay out of the labor force permanently. In particular, we investigate the role of human capital-loss and -rebuilding in determining the transition from unemployment into employment or non-participation.

The model assumes that human capital, i.e. a person's skills, experience and knowledge, determines the wages of the employed. Human capital degrades while not employed, thus reducing future labor market earnings. However, the unemployed can make costly investments to re-train and thus mitigate human capital degradation. Investments in human capital can be optimal if an unemployed person plans to re-enter the labor market at a later stage but not if the person plans to remain out of work permanently. We elaborate on the determinants of why some never obtain benefits, some obtain benefits for a limited time, and some become dependent on dole money permanently. In this sense, we provide a human capital model of welfare careers or social benefit dependency. As in much of the literature, we assume quite unrealistically perfect foresight about the benefit system and the future labor market prospects in the first part of the paper, but relax this assumption later in two ways. First, we allow shocks to the wages to be non-anticipated and, second, we demonstrate the possibility of an unemployment trap. Our account of the unemployment trap is based on the assumption of time-inconsistent preferences which may induce the unemployed to postpone re-training until it is too late (for an alternative account based on welfare cultures see Lindbeck et al. 1999). In both cases, people may end up on the dole permanently, against their best intentions.
Understanding the determinants of non-participation in the labor market is important because benefit dependency rates are large. For example, benefit dependency rates, i.e. the proportion of people receiving an income-replacement benefit, are today about twice as large as the share of people on unemployment benefits in OECD countries, and benefit dependency rates have continued to increase in the 1990s in many OECD countries (Carcillo and Grubb, 2006). For example, the number of social assistance recipients in France (the RMI was introduced in 1989) grew by 45% between 1993 and 2000, even though this was a period of cyclical upswing (OECD 2003: 187). The available empirical evidence suggests that welfare benefits are an important determinant of non-participation. For example, Card and Robins (1998) found strong effects of welfare benefits on labor force participation in Canada in an experimental setting (see Krueger and Meyer 2002 for a survey of the effects of out-of-work benefits in selected OECD countries). Benefit dependency rates vary considerably across countries. For example, benefit dependency among people of working age is about one third of employment in 6 EU countries, but higher in e.g. France and Germany and lower (one fifth) in others like Spain and the US (OECD 2003: 174). This variation suggests that the interaction of unemployment and welfare benefits, as well as country-specific labor market prospects need to be taken into account in explaining non-participation. We therefore believe that understanding non-participation requires a unified analysis within a framework of employment, decisions to re-train, and unemployment. Using such a framework allows the researcher to scrutinize if measures to move people off unemployment benefits run the risk of increasing flows into welfare benefits, rather than into jobs.

Our human capital model is rich in that it generates a large number of empirically plausible direct and interaction effects, while being simple enough to be represented in a single graph. We believe our model provides an attractive complement to other theoretical accounts of non-participation which are often more complex.

Our model of non-participation is based on human capital loss through skill degradation during non-employment. Skill degradation is frequently invoked as an intuitive explanation of long-term unemployment (e.g. Ljungqvist and Sargent, 1998) and complements other explanations based on insider-outsider effects of wage determination (Lindbeck and Snower, 1988), habit formation (Vendrik, 1993), and stigmatization or scarring effects. See Roed (1997) and Cahuc and Zylberberg (2004) for overviews and Bean (1994) for a critical comparison of supply- and demand-side mechanisms in explaining European unemployment and its persistence. Demand-
side effects of skill loss during unemployment are investigated by Pissarides (1992) and Coles and Masters (2000).

The decision to live on welfare benefits permanently, i.e. as long as current labor market frictions and institutions do not change, relates our model to the literature that investigates the effects of welfare benefits on extensive and intensive labor supply (for example, Moffitt, 1983, Lindbeck et al., 1999, see Moffitt, 2002, for a survey). There seems to be an emerging consensus that extensive labor supply responses are much stronger than intensive responses (e.g. Heckman 1993. See Immervoll et al. 2007 for a discussion of European countries). In contrast to that literature we focus here on a unified three-status analysis of employment, unemployment, and non-participation as an outcome of the interplay of labor market institutions and individual characteristics like age and skill depreciation.

Our human capital-based model of non-participation is distinct from but related to the small literature extending the search and matching model towards a third state of non-participation (McKenna, 1987, Sattinger, 1995, Pissaridis, 2000, ch. 7, Garibaldi and Wassmer, 2005). According to this approach individuals trade off the time spent on searching for a job against leisure and some of them decide against searching (perhaps discouraged by the belief that their search productivity is low, see Falk et al., 2006 or Frijters and van der Klaauw, 2006). The main difference to our model is that there non-searching people would accept a job offer that comes without searching. In other words, while the non-participating individuals are not searching actively, they are nevertheless waiting for a job, i.e. they are "passively searching" (Jones and Riddell, 1999). In contrast, our model assumes that jobless individuals could get a new job immediately – possibly at a lower wage than in their last job – but prefer, all things considered, to stay on the dole permanently. In our model, non-participation is distinct from unemployment (Flinn and Heckman 1983) and to keep the analysis tractable, it is modeled as an absorbing state (as in Calmfors and Lang 1995). That is, those exiting from unemployment into non-participation do so permanently in the absence of shocks and this transition is modeled as a rational choice.\footnote{Recently, Pavoni and Violante (2007) integrated human capital erosion into the three-state search literature and investigated the optimal design of welfare to work policies. While not finding a job remains the cause of unemployment in their model, their model deviates from the search literature by assuming that the length of unemployment and eventually non-participation is determined – as in our work – through the interaction of human capital and its erosion with labor market institutions.}
We believe that our approach is a useful complement to other theoretical approaches to non-participation because it has several advantages. Our model is rich in that it incorporates a large number of determinants of unemployment and labor force participation; it is simple in that the formal reasoning is tractable and can be graphically displayed in a single diagram, it is flexible in that the model can easily be extended to account for present-biased preferences, and it is accurate in the sense that most of the predictions are in line with stylized empirical facts. These advantages come at the cost of some limitations. Our account is partial as it focuses on the supply-side and is not embedded in a general equilibrium framework, it abstracts from search frictions, and macroeconomic fluctuations are modeled in a highly stylized fashion. On balance, we believe that our model provides an attractive complement to more complex models of unemployment and labor force participation.

We proceed as follows. The model presented in Section 2 builds on the standard assumptions that the decisions whether to participate in the labor market and to retrain depend exclusively on monetary criteria and made in a fully rational and consistent way. Section 3 investigates the comparative statics of changes in unemployment insurance and welfare benefits, socio-economic characteristics, and labor market conditions. Section 4 discusses the determinants of the optimal unemployment spell. Section 5 relaxes the standard assumptions by allowing for time-inconsistent preferences. This opens up the possibility that agents get stuck in an unemployment trap and remain on the dole permanently, against their best intentions.

2. The Model

Consider a person who loses his (or her) job but could get a new job immediately or anytime in the future. The person can either accept the job, earn a wage that depends on his productivity and current labor market conditions, and pay taxes on his wage income. Alternatively, he can remain unemployed. If he stays unemployed he is entitled to receive unemployment benefits depending on the last net wage for a limited time of $\tau$ periods. After that he receives social assistance which is independent of the last wage until the end of his working life. We call a person remaining without job for not more than $\tau$ periods unemployed (henceforth UnEmp) and a person who remains without job for longer than $\tau$ periods non-participating (NonPart for short). The main difference to the three-stage search literature of unemployment is that somebody who stays jobless beyond the short term in our model is neither actively nor passively
looking for a job. In fact, he could get a job without search, but as long as the current labor market conditions and institutions do not change he prefers to stay on the dole.\(^2\)

The cost of being out of work is that human capital erodes, i.e. the jobless face skill degradation. We assume that jobless people can retrain at some cost to mitigate skill degradation. A jobless person thus faces two decisions: when to accept a job (i.e. whether to be employed, unemployed, or non-participating) and whether to mitigate human capital degradation by retraining. As shown in detail below, our model predicts that some (those with high productivity) find it profitable to accept a job and to be employed immediately, and some find it attractive to obtain unemployment insurance for some periods. Of those, some use this time for retraining while others (often those with low skills), find it profitable to let human capital erode and remain on the dole permanently. These decisions depend in subtle ways on labor market institutions, personal characteristics and macroeconomic labor market frictions.

Consider a currently jobless person with human capital (productivity) \( h \) who could get a job at a gross wage \( w_t = h - \lambda_t \). The parameter \( \lambda_t \) measures exogenous shocks to labor market income. We assume that labor income is taxed at a constant rate \( \theta \). It pays for a person with human capital \( h \) to accept a job immediately (i.e. at time \( t = 0 \)) if the present value of life-time labor market income

\[
V(h, 0) = \sum_{t=0}^{T-1} \delta^t (1 - \theta) (h - \lambda_t)
\]

(1)
dominates all other possible income streams. We assume that future income is discounted at factor \( \delta < 1 \), and that the person retires from working life after \( T \) periods. Equation (1) shows that life-time labor market income \( V(0) \) increases with human capital endowment and the length of remaining working life. This implies that \( V(0) \) decreases with the worker’s age.

The cost of being without job is that human capital degrades during this period. This may, for example, be the case because the jobless do not benefit from on-the-job training, because human capital erodes when not familiarized with the current state-of-the-art technology, or simply because they are not used to work anymore.\(^3\) People can mitigate human capital degradation or

\(^2\)Note that all workers are eligible to benefits from unemployment insurance for \( \tau \) periods. The non-participants are in this respect indistinguishable from the unemployed. However, the non-participants continue to be jobless after unemployment insurance benefits expire, i.e. by staying on social assistance.

\(^3\) Topel (1990) estimates that in the US in the 1970s and 1980s workers losing a job suffered on average a wage reduction of between 15 and 40 percent by the time they found a new job. Jacobsen et al. (1993) find similar results. Keane and Wolpin (1997) estimate that blue-collar skills depreciate by about 10 percent in a year absent from work, while white-collar workers lose about 30 percent of their skills during one year of unemployment. Thus, a more realistic model would tie the depreciation rate itself to the level of human capital. In any case,
actually improve skills by incurring costly educational efforts (e.g. by taking a computer course) while being without job. These efforts are valuable because they increase human capital, and thus future wages. To keep the analysis of skill deterioration and retraining tractable, we assume that a fraction \( d \) of human capital depreciates during short-term unemployment and that jobless persons can spend \( c \cdot \bar{e} \) units of income on retraining which increases their human capital by \( e > 0 \) units. Alternatively, they may let their human capital erode and do not retrain \( (e = 0) \).

Jobless people receive benefits \( b \cdot (1 - \theta)h \) from unemployment insurance for \( \tau \) periods. Unemployed persons leave unemployment at time \( \tau \) and receive a wage of \( w_t = (1 - \theta)[(1 - d)h + e - \lambda_t] \) per period \( t \) for the rest of their working life. Thus the present value of life-time income for an unemployed is given by

\[
V(h, \tau) = \sum_{t=0}^{\tau-1} \delta^t b(1 - \theta) h - c \cdot e + \sum_{t=\tau}^{T-1} \delta^t (1 - \theta) [h(1 - d) + e - \lambda_t],
\]

where \( c \) denotes unit costs of retraining (in present value terms).

If people are still without a job after \( \tau \) periods, they receive tax-exempt social assistance \( s \) per period until time \( T \). The present value of life-time income of a non-participant who has just lost his job includes unemployment insurance benefits received over the first \( \tau \) periods and is given by

\[
V(h, T) = \sum_{t=0}^{\tau-1} \delta^t b(1 - \theta) h + \sum_{t=\tau}^{T-1} \delta^t s.\]

A person’s life-time income \( V(h, t) \) can be understood as a function of his human capital and the time \( t \) at which he ceases to be jobless (by either entering employment or retirement). To keep the analysis simple, we assume that \( \lambda_t \) can take two values: \( \lambda_0 \), representing contemporaneous labor market shocks and \( \lambda_T \) denoting expected labor market frictions that occur between time \( \tau \) and \( T \). To simplify the notation, we introduce the following aggregated discount factors.

\[
\delta_\tau \equiv \sum_{t=0}^{\tau-1} \delta^t = \frac{1 - \delta^\tau}{1 - \delta}, \quad \delta_T \equiv \sum_{t=\tau}^{T-1} \delta^t = \delta^\tau \cdot \frac{1 - \delta^{T-\tau}}{1 - \delta}.
\]

However, human capital degradation is of non-negligible magnitude.

There is no uncertainty in the model. We thus abstain from modelling the possibility to lose the accepted job again. This possibility could, however, be integrated into the model without changing any qualitative results, i.e. it only increases analytical complexity. Note that our model does not imply that the person will never lose his job again. It only implies that this event, if it occurs, comes unexpected in form of an exogenous shock. Likewise, our model does not imply that non-participants stay out of the labor market forever. If they re-enter, however, this comes as a reaction to an exogenous event of, for example, a favorable macroeconomic shock or an unexpected reduction in the generosity of social assistance.
Note from inspection of equations (4) that a longer working-life increases $\delta_T$ and leaves $\delta_\tau$ unaffected, while longer duration of eligibility for unemployment benefits increases $\delta_\tau$ and reduces $\delta_T$ in equal proportions, $\partial \delta_\tau / \partial \tau = -\partial \delta_T / \partial \tau > 0$. With these notational simplifications we can analyze career decisions conveniently in a $h-V$-diagram taking the exit time from unemployment $t \in \{0, \tau, T\}$ parametrically. For this purpose we rewrite (1') – (3') as

$$V(h,0) = \delta_\tau (1 - \theta) (h - \lambda_0) + \delta_T (1 - \theta) (h - \lambda_T) \quad (1')$$
$$V(h,\tau) = \delta_\tau b (1 - \theta) h - c \cdot e + \delta_T (1 - \theta) [(1 - d) h + e - \lambda_T] \quad (2')$$
$$V(h,T) = \delta_\tau b (1 - \theta) h + \delta_T s. \quad (3')$$

The decision to retrain is straightforward. Equation (2') reveals that life-time income of the UnEmp is higher with retraining ($e > 0$) than without ($e = 0$) if the present value of the labor income gain exceeds the present value of retraining costs. In particular, $e > 0$ is chosen if

$$c < (1 - \theta) \delta_T. \quad (5)$$

Otherwise, no retraining takes place, i.e. $e = 0$. Thus, equation (5) captures the empirically plausible effects that high labor taxes discourage retraining and that younger workers (i.e. those with higher $\delta_T$) tend to do more retraining than older workers. Mitigating human capital degradation is never optimal for the non-participants because they expect not to return into employment and not to reap the returns of retraining.

A natural assumption (which holds for every OECD country, see OECD, 1999) is that the net market wage is higher than unemployment insurance benefits, i.e. that the replacement rate $b$ is smaller than 100 percent. Under this condition, life-time income is always more steeply increasing in human capital for employed persons than for unemployed persons. For the unemployed, in turn, life-time income increases more steeply in $h$ than for the non-participating.

$$V(h,0)' = \delta_\tau (1 - \theta) + \delta_T (1 - \theta) > V(h,\tau)' = \delta_\tau (1 - \theta) b + \delta_T (1 - \theta) (1 - d) > V(h,T)' = \delta_\tau (1 - \theta) b. \quad (6)$$

Thus, in a $V-h$ diagram, life-time income intersects in three points yielding critical levels of
human capital. These intersections are calculated from (1’ – (3’):

\[ h^A = \frac{\delta_T [s + (1 - \theta)\lambda_T] - e [(1 - \theta)\delta_T - c]}{\delta_T(1 - \theta)(1 - d)} \] (7)

\[ h^B = \frac{(1 - \theta) [\delta_T\lambda_0 + \delta_T\lambda_T] + s\delta_T}{(1 - \theta) [\delta_T(1 - b) + \delta_T]} \] (8)

\[ h^C = \frac{\delta_T(1 - \theta)\lambda_0 + e [(1 - \theta)\delta_T - c]}{(1 - \theta) [\delta_T(1 - b) + \delta_Td]} \] (9)

We call the intersection between \( V(h, \tau) \) and \( V(h, T) \) point A, the intersection between \( V(h, 0) \) and \( V(h, T) \) point B, and the intersection between \( V(h, 0) \) and \( V(h, \tau) \) point C (see Figure 1).

Figure 1: Career Decision Diagram

Figure 1 reflects several well-known empirical regularities. First, unemployment decreases with education (see e.g. OECD, 2004). Second, non-participation is more prevalent among low-skilled workers. For the latter, human capital, i.e. productivity, is so low that the best available choice is to live on the dole permanently. In our model, this is in particular the case when labor

\footnote{It is also possible according to (6) that it is never optimal to be UnEmp, i.e. people are either employed or NonPart. This empirically less plausible, degenerate case is discussed in the Appendix.}
market prospects are currently bleak and will remain so in the future (high $\lambda_0$ and $\lambda_\tau$), and when social benefits ($s$) are generous.$^6$

Education and employment go hand in hand, according to the empirical literature. For example, Nickell (1979) and Machin and Manning (1999) show that unemployment duration falls with education. Yet, in our setup becoming NonPart means a complete exit from the labor force. In other words, the decision to participate in the labor market again (triggered, for example, by a change of social assistance, taxation, or a favorable labor market shock) affects labor supply at the extensive margin. Our result that non-participation is – ceteris paribus – observed for people with low skills and low productivity is in line with the empirical regularity that extensive labor supply elasticities are particularly large at the low end of the income distribution (Eissa and Liebman, 1996 and Meyer and Rosenbaum, 2001). A positive relationship between education and participation rates is also documented in OECD (2004).

On the upper end of the education spectrum we find those workers who never prefer to be unemployed because the opportunity costs of unemployment (in terms of human capital degradation and future wage loss) are too high. For intermediate skill-levels a period in unemployment is optimal if $h^A$ is located to the left of $h^C$. For the UnEmp it pays to let human capital erode if unemployment benefits are relatively generous, if human capital does not erode much, or if the unemployment spell is actually used to retrain and to upgrade human capital.

Unemployment is optimal if retraining pays off, i.e. when (5) holds. In that case there are always some persons who find it optimal to retreat from the labor market to acquire additional human capital. In order to obtain the condition that there is unemployment without retraining, insert (7) and (9) and $e = 0$ into $h^A < h^C$ to get:

$$\lambda_\tau + \frac{s}{1-\theta} < \frac{\delta_\tau \lambda_0 (1 - d)}{\delta_\tau (1 - b) + \delta_T d}$$

Thus, unemployment is more likely to be observed when the opportunity costs of being unemployed are low, i.e. when adverse labor market shocks are currently large (large $\lambda_0$) but are expected to be low in the future (small $\lambda_\tau$), when the direct cost in terms of human capital degradation are low (low $d$), when the benefits for unemployment ($b$) are generous and granted

$^6$ Note that we compare income streams and do not consider how utility is affected by stigma effects or by time availability – be it positively via leisure or negatively via reduced self-esteem. See Moffit (2002) for the standard model on the effect of leisure preferences for welfare recipients and Darity and Goldsmith (1996) for an overview on the effects of joblessness on emotional well-being. See Moffitt (1983) on stigma. Note that stigma and leisure effects could be easily introduced parametrically into our model, i.e. as shift parameters of $V(h, T)$ and $V(h, \tau)$.  

9
for a long period (i.e. \(\delta_{\tau}\) is large), and when exiting unemployment after some time is relatively attractive (i.e. social assistance (s) is low, and taxes on labor income (\(\theta\)) are not too high). Equation (10) also shows that, ceteris paribus, unemployment without re-education is more prevalent among older workers (i.e. for low \(\delta_{T}\)).

3. **Comparative Statics**

We now discuss how labor market institutions (in particular, the generosity of unemployment benefits \(b\), duration of eligibility for unemployment benefits \(\tau\), labor market taxes \(\theta\), generosity of social assistance \(s\)), the characteristics of the jobless (in particular, human capital \(h\), skill loss \(d\), age \(T - \tau\), retraining costs \(c\)) interact with adverse contemporaneous (\(\lambda_0\)) or expected (\(\lambda_{\tau}\)) labor market shocks to explain retraining and the decision to stay temporarily or permanently on the dole. By differentiating the functions (7) and (9) with respect to the model’s institutional and individual parameters we obtain how \(h^A\) and \(h^C\) change their position in the career diagram, providing comparative statics of individual career decisions. If we imagine a country’s (or region’s) workforce ordered along the \(h\)-line according to their human capital endowment, we can infer the comparative statics of aggregate unemployment and labor force participation.

3.1. **Unemployment Benefits.** In line with empirical evidence, we find that a higher replacement rate \(b\) increases overall unemployment (e.g. Nickell et al., 2005). In Figure 1, an increase in \(b\) leaves \(h^A\) unaffected and shifts \(h^C\) to the right.

\[
\frac{\partial h^A}{\partial b} = 0, \quad \frac{\partial h^C}{\partial b} = \frac{\delta_{\tau} h^C}{\delta_{\tau}(1-b) + \delta_{\tau}d} > 0.
\]

Higher unemployment benefits increase unemployment because they increase the incentive to let human capital erode for a while or to use an unemployment spell for the accumulation of new skills. The model predicts that workers with low human capital degradation (\(d\)) and old workers (small \(\delta_{T}\)) are particularly responsive to changes in unemployment benefits.

3.2. **Duration of Eligibility for Unemployment Benefits.** The effects of an increase in the duration of eligibility for unemployment benefits are less straightforward. A longer period of unemployment benefits increases non-participation if it discourages the unemployed to retrain. Without retraining (\(e = 0\)) a change in duration has no effect on labor force participation. An increased duration of benefits increases unemployment under some conditions (in particular
when taxes and adverse labor market shocks are high). To simplify the notation, we define $\delta' \equiv \partial \delta_r / \partial \tau > 0$ and recall that $\partial \delta_T / \partial \tau = -\delta'$. We obtain the following effects of increasing the duration of eligibility for unemployment benefits ($\tau$).

$$\frac{\partial h^A}{\partial \tau} = \frac{ce\delta'}{\delta^2_T(1-\theta)(1-d)} \geq 0, \quad \frac{\partial h^C}{\partial \tau} = \frac{(\delta_r + \delta_T)\lambda_0(1-\theta)d - \phi \cdot e}{(1-\theta)[\delta_r(1-b) + \delta_Td]^2} \cdot \delta'$$

$$\phi \equiv [(1-\theta)\delta_T - c](1-b) + (1-\theta)(1-b)\delta_r + cd > 0,$$

where the positivity of $\phi$ follows from the retraining condition (5).

Suppose unemployment is not used for retraining ($e = 0$). In this case, longer eligibility for unemployment benefits does not affect the decision to be NonPart (because for non-participation it is optimal to stay on the dole permanently anyway). It increases unemployment because some workers in the higher range of the education spectrum find a short spell in unemployment attractive ($\partial h^C / \partial \tau > 0$ for $e = 0$). This will in particular be the case when current labor market frictions are large. Without labor market frictions ($\lambda_0 = 0$) and without retraining, there is no effect of benefit eligibility on unemployment because the replacement rate is smaller than one (i.e. $1 - \theta - b > 0$).

If workers retrain, their option to upgrade skills is the dominant motive for being unemployed (rather than to collect unemployment benefits). In this case, our simplified model which treats retraining as a one-time event that happens instantly (by paying the retraining cost) may imply a degenerate reaction to longer eligibility of unemployment benefits. Having used the unemployment spell for retraining, workers actually strive for a new job because the payoff of the newly acquired skills in terms of higher wages occurs only after re-employment.

An (exogenous) extension of the unemployment period $\tau$ has thus the negative effect of delaying re-employment. The delay devalues retraining such that some workers with intermediate skills who would have retrained with a shorter duration now decide against retraining. Without retraining, they find a permanent stay on the dole attractive and as a consequence the range of NonPart increases at the expense of UnEmp ($\partial h^A / \partial \tau > 0$ for $e > 0$).

An exogenous extension of the eligibility period $\tau$ also affects workers with relatively high skill levels. These workers would also have chosen to use an unemployment spell to invest in human capital, but with a higher $\tau$, they find this option less attractive than entering employment. The derivative of $h^C$ shows that devaluation of retraining is the dominant effect on unemployment.
if taxes are low and labor market are not much distorted by adverse shocks (since both further increase the value of being quickly employed again). While this interpretation of exogenous changes of $\tau$ on human capital are fairly intuitive, the reverse interpretation is perhaps more plausible. In this case, $\tau$ is interpreted as decision variable depending on $h$. Interpreted in this way, the derivative shows that a worker’s preferred duration of unemployment for retraining purposes decreases with his initial endowment of human capital, $\partial \tau / \partial h^C < 0$. In Section 4 we investigate the decision on unemployment duration in detail.

The “normal” reaction of increasing unemployment for increasing duration of unemployment benefits payments $\partial h^C / \partial \tau > 0$, is obtained when market frictions and taxes are sufficiently high. In this case, longer eligibility makes unemployment more attractive and employment decreases. In other words, interaction terms matter (see Belot and van Ours, 2004, and Nickell et al., 2005). In a U.S.–style welfare system where $\lambda_0$ is small and $\phi$ is large (because taxes $\theta$ and benefits $b$ are low), the effect of longer eligibility on unemployment will be small and possibly ambiguous. In a European–style welfare state where $\lambda_0$ is large and $\phi$ is small the effect of benefit eligibility on unemployment is positive and possibly large.

3.3. Social Assistance. Higher social assistance changes labor force participation and through this channel the overall level of unemployment. It reduces participation because some low-skill unemployed individuals find it now attractive to remain on the dole permanently. In Figure 1, an increase in social assistance moves $h^A$ to the right and leaves $h^C$ unaffected.

$$\frac{\partial h^A}{\partial s} = \frac{1}{(1 - \theta)(1 - d)} > 0, \quad \frac{\partial h^C}{\partial s} = 0$$

Workers at the upper end of the education spectrum may consider to use an unemployment spell for some further retraining but staying permanently on the dole is never an option for them. Thus, the decision between employment and unemployment is unaffected by a change in social assistance ($\partial h^C / \partial s = 0$). But some workers who previously planned only a short spell of unemployment will find the status of NonPart attractive when social assistance increases. The derivative $\partial h^A / \partial s$ indicates that this effect will be large for those with high rates of human capital degradation.

Some researchers hold generous social assistance responsible for continental Europe’s employment problem. A single NonPart without children, for example, who would live on food stamps
in the U.S. receives in Germany Sozialhilfe of 648 Euros per month (including support for housing and heating). Sozialhilfe for other types of households is higher. A couple with two children, for example, receives on average 1601 Euros per month. Several other European countries operate social assistance of comparable generosity (European Commission, 2004). For Germany, Boss (2001) and Sinn et al. (2002) calculate marginal tax rates on (potential) low-wage income of the recipients of social assistance between 80 and 100 percent. Sinn et al. conclude that it does not pay to work for a head of a West German household with two children if his or her productivity is below 50 percent of average productivity.

In the career decision diagram more generous social assistance shifts $h^A$ to the right. This moves social assistance above net wage income for a larger fraction of the $h$-ordered population and increases the range of NonPart in the low-productivity segment of the labor market. The magnitude of this effect is predicted to be large when taxes on (potential) labor income are high.\footnote{Of course, the policy conclusion to be drawn is not that $s$ should be lower but that it should not be paid conditionally on the status of non-participation.}

3.4. **Taxation.** Higher taxes on labor income increases non-participation because they discourage some low-skill unemployed to accept a job after running out of unemployment benefits. Higher taxes also make retraining for high-skill persons less profitable. In Figure 1, a higher tax rate on labor income $\theta$ moves $h^A$ to the right and shifts $h^C$ left, if anything.

\[
\frac{\partial h^A}{\partial \theta} = \frac{\delta_T s + ce}{\delta_T (1 - \theta)^2 (1 - d)} > 0
\]

\[
\frac{\partial h^C}{\partial \theta} = -\frac{ce}{(1 - \theta)^2 [\delta_T (1 - b) + \delta_T d]} \leq 0.
\]

Higher taxes reduce the net payoff from working and increase the range of NonPart. Note that the effect is particularly strong if retraining is, in principle, worthwhile ($e > 0$). Some low-productivity workers who would have used an unemployment spell to upgrade their skills when taxes are low are now facing a lower net return of re-education after the tax increase and prefer to stay on the dole permanently. Furthermore, the effect is strong if taxes are already high, if social assistance is generous, and if skills degrade rapidly during unemployment.

Because non-participants are also counted as unemployed during the first phase of their joblessness, the model suggests that higher taxes reduce the incidence of short-term unemployment at
the expense of non-participation. Moreover, lower net returns of retraining also apply to workers of intermediate productivity who previously considered an unemployment spell and now prefer to exit unemployment immediately. Thus short-term unemployment is reduced for two reasons: an outflow into employment of workers from the higher productivity segment and an outflow into non-participation of workers from the lower productivity segment who are permanently discouraged by higher taxes.

We now discuss how personal characteristics of the unemployed determine retraining and the duration of the stay on the dole. As explained below, some variables which are interpreted as reflecting personal characteristics might also be interpreted as due to policy choices. For example, the effect of the variable “remaining work-life” might be interpreted as a worker’s age or as (mandatory) retirement age.

3.5. Human Capital Degradation. The rate at which a worker’s human capital erodes can depend on his personal characteristics, i.e. on his skill level, or be a consequence of exogenous factors like the rate at which technological innovations are made. Rapid degradation of human capital increases the range of non-participation because retraining is less attractive for the unemployed, and it reduces the share of UnEmp because the costs of skill degradation while unemployed are too high for high-skill workers. In Figure 1, higher human capital degradation during unemployment moves $h^A$ to the right and $h^C$ to the left.

\[
\frac{\partial h^A}{\partial d} = \frac{s + \lambda_T (1 - \theta) - e [(1 - \theta) \delta_T - c]}{\delta_T (1 - \theta) (1 - d)^2} = \frac{h^A}{(1 - d)} > 0, \quad \frac{\partial h^C}{\partial d} = -\frac{\delta_T (1 - b) + d}{\delta_T} < 0.
\]

Hence, rapid human capital degradation reduces short-term unemployment at both ends. Some workers from the upper end of the education spectrum who previously thought about using a spell of unemployment to upgrade their human capital, now decide against it because the opportunity costs of skill loss while not working are too high. At the lower end of the educational spectrum some workers who previously found a short spell of unemployment attractive, now see their human capital (and potential future wages) erode so fast that staying permanently out of work becomes attractive.

It is worthwhile to point out differences of effects of human capital degradation in our model and the model by Ljungqvist and Sargent’s (1998). In their model increased turbulence, modelled as increasing skill depreciation $d$ (as observed in the 1980’s) has a strong effect on unemployment.
in countries with high unemployment insurance benefits compared to a laisser-faire economy. Here we find that it are not high unemployment insurance benefits that are identified as the main amplifier of skill-degradation effects but high social assistance ($s$), high expected labor market friction in the future (high $\lambda_T$), and high labor income taxes or, more generally, a large welfare state.

Second, Ljungqvist and Sargent’s study obtains that in particular workers with high initial skill level (high pre-unemployment wage) choose to stay unemployed for a while (i.e. search with low intensity for a new job) in times of turbulence. In contrast, our analysis finds that employment increases in the high-skill segment when $d$ increases because the opportunity costs of skill-loss are too high in turbulent times. In fact our analysis suggests that overall short-term unemployment decreases as a response to increasing turbulence. According to our model, the “European disease” is manifested in decreasing participation rates and an increasing share of workers from the lower end of the skill distribution who find a permanent life on the dole attractive when times are turbulent.

Finally, we can derive a result with respect to working-age. The derivative of $h^C$ is increasing in $\delta_T$ in absolute terms. Thus, the positive effect on employment operates among the youth (with a long remaining work life $T - t$) who exit unemployment earlier under the threat of rapid skill degradation. On the other end of the education spectrum we find that $h^A$ is decreasing in $\delta_T$ implying that the pool of non-participants is in particular filled by older workers close to retirement age who face a lower threat of skill degradation. Our result is supported by the observation that labor force participation in Europe decreased in particular within the group of older and less educated workers (Bloendal and Scarpetta, 1999).

3.6. Retraining Costs. An increase in retraining costs discourages retraining among the UnEmp and therefore increases NonPart. In Figure 1, higher retraining costs $c$ shift $h^A$ to the right and $h^C$ to the left.

$$\frac{\partial h^A}{\partial c} = \frac{e}{\delta_T(1 - \theta)(1 - d)} \geq 0, \quad \frac{\partial h^C}{\partial c} = -\frac{e}{(1 - \theta) [\delta_T(1 - b) + \delta_Td]} \leq 0.$$  

Obviously, an increase in retraining cost has no effects if retraining does not take place ($e = 0$). With retraining, unemployment is reduced at both ends when $c$ rises. At the upper end of the education spectrum, some workers who previously considered an unemployment spell to upgrade
their skills now find that they cannot afford it and stay employed. Retraining becomes also too expensive for some at the lower end of the education spectrum. For those persons, however, it is then the best choice to stay out of work permanently.

While retraining costs can be determined by personal characteristics, they may also importantly depend on labor market policy. For example, retraining costs can be reduced by subsidies for (re-)education. Our model suggests a short-run increase of unemployment due to subsidies for retraining. The policy only reduces unemployment in the long run, i.e. when workers re-enter employment who were motivated by the retraining subsidy to leave the status of NonPart (reflected by the move of \( h^A \) to the left). Note that retraining subsidies are particularly effective for persons with rapid human capital degradation since \( \partial h^A / \partial c \) increases and \( \partial h^C / \partial c \) decreases in absolute terms when \( d \) rises.

### 3.7. Age.

Comparative statics of increasing working-life \( T \) and, thus, a larger discount factor \( \delta_T \) depend on a number of factors in subtle ways. The derivatives are

\[
\frac{\partial h^A}{\partial \delta_T} = -\frac{ce}{\delta_T^2(1-\theta)(1-d)} \leq 0, \quad \frac{\partial h^C}{\partial \delta_T} = \frac{e - dh^C}{\delta_T(1-b) + \delta_T d}.
\]

The duration of working life can be analyzed in a cross-sectional perspective distinguishing between younger and older workers or in a time-series perspective when investigating exogenous events like an increase in retirement age. In analyzing the effects of a longer work life on employment, we distinguish two cases.

When retraining does not pay off \((e = 0)\), the effects of an increased duration of working life are clear. In this case, our model predicts no effect on NonPart because low-productivity workers prefer to stay on the dole permanently anyway. Yet, an increase in the length of working life induces an increase of employment, i.e. a reduction of UnEmp \((\partial h^C / \partial \delta_T < 0 \text{ for } e = 0)\). The reason is that a longer working life increases the present value of a permanent loss of human capital during an unemployment spell. Therefore, the status of UnEmp becomes more threatening and some additional workers with intermediate skills accept a job immediately.

With retraining being worthwhile \((e > 0)\), an increase in work-life affects UnEmp because it extends the time during which the fruits of retraining are reaped and thus makes an unemployment spell for the purpose of retraining attractive. If the retraining effect dominates (reflected by relatively high \( e \)), unemployment increases as a response to a longer working life; if the human
capital degradation effect dominates (reflected by relatively high \( d \)) it decreases.

In any case, however, a prolonged working life reduces non-participation when retraining is worthwhile. Some of the workers from the lower end of the productivity spectrum who previously settled on a life on the dole find retraining attractive when the fruits of the educational effort are reaped through a longer working life. This result suggests a strong policy conclusion: Early retirement cannot be a solution of the employment problem (as some western European authorities seem to have believed in the 80’s and 90’s). Quite the opposite is true according to the model. Another way of putting this result is that the status of NonPart is particularly attractive for older workers (with small \( \delta_T \)). Furthermore, the derivative of \( h^A \) shows that the incentive to stay on the dole permanently will be strong for older workers when skills erode rapidly and labor income taxes are high.

3.8. Labor Market Frictions. Fluctuations in labor markets are reflected in deviations \( \lambda_t \) of actual wage income from wages paid under “normal” circumstances, \( w_t = h \). We model macro-economic labor market frictions as resulting from exogenous events. These can be temporary, perhaps due to a downturn in the business cycle, or persistent, perhaps due to structural shifts in labor demand. A contemporaneous and temporary recession is captured by an increase in \( \lambda_0 \), and an expected recession by an increase in \( \lambda_\tau \). A permanent structural change is modelled by imposing \( \lambda_0 = \lambda_\tau \). The corresponding derivatives are

\[
\frac{\partial h^A}{\partial \lambda_0} = 0, \quad \frac{\partial h^C}{\partial \lambda_0} = \frac{\delta_\tau}{\delta_\tau(1-b) + \delta_T d} > 0
\]

\[
\frac{\partial h^A}{\partial \lambda_\tau} = \frac{1}{1-d} > 0, \quad \frac{\partial h^C}{\partial \lambda_\tau} = 0.
\]

In line with standard intuition, a contemporaneous temporary recession increases unemployment and leaves non-participation unaffected. The effect on unemployment is particularly large if unemployment benefits are high and granted for a long period (\( \delta_\tau \) is large). The effect is particularly pronounced among older workers (with low \( \delta_T \)). A possibly more surprising prediction of our model is that an expected future downturn of the economy (i.e. higher \( \lambda_\tau \)) increases non-participation. A pessimistic outlook reduces the incentive to retrain during unemployment, and some workers of the current unemployment pool decide against retraining. Without retraining, their productivity falls to a level that makes a permanent life on the dole attractive. This effect is particularly strong if human capital erodes rapidly.
An adverse structural change, perhaps due to a fall in international competitiveness, is modelled by higher $\lambda_0 = \lambda_T$ and is obtained as the sum of both effects discussed above. The structural change will thus unambiguously increase non-participation and reduce employment. The effect on (short-term) unemployment depends again on whether the inflow into unemployment dominates the outflow into non-participation. A comparison of derivatives shows that this is the case if

$$\left(1 + \frac{\delta_T}{\delta_T}\right) \cdot d < b,$$

i.e. if human capital erosion is relatively small compared to unemployment benefits. In this case, incentives are high enough for skill-upgrading to be the predominant motive for unemployment.

4. Endogenous Unemployment Duration

The focus of investigation of this paper has been the decision of being employed, unemployed, or out of the labor force. It has thus addressed a different question than the standard search-and-matching literature which focusses on the duration of unemployment (given the status of being unemployed). In order to relate our model to this literature we now show how the length of the unemployment spell as a decision variable depends on individual characteristics and labor market institutions. While search models explain unemployment with the opportunity costs of leisure or foregone home production while searching for a new job, our model explains unemployment with current labor market frictions and the gains from retraining which are traded off against the opportunity cost of skill degradation. Interestingly, although our motivation is different, we nevertheless arrive at similar comparative statics with respect to unemployment duration as the search literature.

As a starting point we take that unemployment has been the optimal choice according to the model from the previous section and assume that the UnEmp actually prefers to stay unemployed for a shorter time $t$ than his eligibility for benefits $b$ is, i.e. $t < \tau$. Otherwise, we would be back to the original model. For a meaningful analysis we have to subdivide the depreciation of human capital among the periods of the actual length of the unemployment spell. Let $\Delta$ denote the depreciation rate per unit length of period (day or week of unemployment). Thus human capital is $(1 - \Delta)^t \cdot h$ at time $t$ when the unemployed accepts a job, with $(1 - d) = (1 - \Delta)^\tau$ if he stays unemployed until he loses eligibility, i.e. $d \equiv 1 - (1 - \Delta)^\tau$. 
Any interior solution $t$ maximizes
\[
\max_t \frac{1 - \delta^t}{1 - \delta} \left[ b(1 - \theta)h - ce - \delta^t \frac{1 - \delta^{T-t}}{1 - \delta} (1 - \theta) \right] (1 - \Delta)^t h + e - \lambda_T].
\]

It fulfills the first order condition
\[
-\delta^t \log(\delta) bh + \delta^t \left[ (1 - \Delta)^t h + e - \lambda_T \right] \log(\delta) - (\delta^T - \delta^t)(1 - \Delta)^t h \log(1 - \Delta)^t = 0
\]
implying that it solves the implicit function
\[
G = \psi \left[ (1 - \Delta)^t h + e - \lambda_T - bh \right] - (\delta^T - \delta^t)(1 - \Delta)^t h = 0
\]
with $\psi \equiv \log(\delta)/\log(1 - \Delta) > 0$. After some algebra the derivative w.r.t. $t$ is obtained as
\[
\frac{\partial G}{\partial t} = (1 - \Delta)^t h \left[ \psi (1 + \delta^{T-t}) + 1 - \delta^{T-t} \right] > 0.
\]
The derivative with respect to $b$ is straightforward: $\partial G/\partial b = -\psi h < 0$. And, applying the implicit function theorem, $\partial t/\partial b = -[\partial G/\partial b]/[\partial G/\partial t] > 0$. Thus, a higher replacement rate $b$ causes a longer stay in unemployment.

Likewise we obtain $\partial t/\partial \lambda_T > 0$ and $\partial t/\partial e < 0$ indicating that higher labor market frictions lead to longer unemployment while higher marginal returns from education reduce the length of the desired unemployment spell. Particularly interesting is the derivative with respect to human capital.
\[
\frac{\partial G}{\partial h} = (1 - \Delta)^t \left[ \psi + 1 - \delta^{T-t} \right] - b,
\]
which is generally ambiguous. Note that $\partial G/\partial h < 0$ and thus $\partial t/\partial h > 0$ is more likely for large $b$, low $\psi$ (i.e. low $\delta$ and low $\Delta$) and for small $T$. Thus, the possibility that a high skilled worker, ceteris paribus, prefers to stay unemployed for a longer time than a low skilled worker worker (the Ljungqvist and Sargent result for turbulent times) rises according to our model with the generosity of benefits. It decreases with the rate of skill depreciation and the rate of time preference and it increases with age. In other words, high skilled workers prefer shorter stays in unemployment if they are young and when the threat of skill degradation with respect to potential future work income is large.
5. Present-Biased Preferences and the Unemployment Trap

In this section we return to the original model but relax the assumption on optimizing behavior by allowing for present-biased preferences. Such preferences seem to be common and imply time-inconsistent behavior, such as procrastination (Laibson 1997 and O’Donoghue and Rabin 1999). Allowing for such preferences enables us to extend the model to account for the possibility of an unemployment trap in which people end up on the dole permanently, against their best intentions. The unemployment trap we demonstrate is a consequence of mistaken intertemporal optimization.

Reconsider the case where retraining costs are sufficiently low and people are sufficiently young such that retraining, in principle, pays off, i.e. condition (5) holds. Diagrammatically, those with human capital below $h_A$ are NonPart and those with human capital exceeding $h_C$ take up employment immediately in Figure 2. The interesting group consists of those with intermediate human capital endowment, $h_A < h < h_C$, who enter unemployment with the intention to upgrade their skills and re-enter employment later.

The duration of unemployment can be subdivided in $\tau$ subperiods of eligibility for unemployment benefits, which can conveniently be thought of as weeks or months. Suppose that it takes one subperiod to upgrade the skills, for example, by taking a computer course and suppose that some individuals have present-biased preferences (Laibson, 1997, O’Donoghue and Rabin, 1999). Thus, the present value of life-time income (2’) for an UnEmp can be rewritten as

$$V_t(h, \tau) = b(1-\theta)h - k_t \cdot c \cdot e$$

$$+ \beta \left\{ \sum_{s=1}^{\tau-1-t} \delta^s \left( b(1-\theta)h - k_s \cdot c \cdot e \right) + \sum_{s=\tau-t}^{T-1-t} \delta^s (1-\theta) \left[ (1-d)h + \left( \sum_{i=0}^{\tau-1} k_i \cdot e \right) \right] \right\}$$

with $\beta \leq 1$ and where $k_t$ is an indicator function that takes a value of $k_t = 0$ in any subperiod without retraining and $k_t = 1$ in the retraining subperiod. If retraining happens, then $\sum k_t = 1$ and $\sum k_t = 0$ otherwise. The only but crucial difference between (11) and (2’) is that now the discount factor from today to the next subperiod is $\beta \delta$ whereas $\delta$ remains the discount factor.

---

8 The assumption that it takes one subperiod to re-educate is made for simplicity and could be generalized. The crucial underlying assumption is that retraining has to be taken up once (or never) during unemployment. DellaVigna and Pasermann (2005) integrate present-biased preferences into a search and matching model. They find (theoretically and empirically) a negative effect of impatience on search intensity and exit from unemployment.

9 Since the argument is independent from labor market shocks we dropped the $\lambda$’s in (11) for convenience.
between any two subperiods in the future.

During unemployment people move from subperiod $t = 0$ to subperiod $\tau - 1$. We first consider the case in which individuals have perfectly time-consistent preferences ($\beta = 1$) as a benchmark. In this case, people rationally postpone retraining until the ultimate period of UnEmp status and then retrain ($k_{\tau-1} = 1$) if retraining is worthwhile, i.e. if

$$c < (1 - \theta)\bar{\delta}_T \equiv (1 - \theta)\frac{\delta(1 - \delta^{T-1-\tau})}{1 - \delta}.$$  (12)

Except for the determination of the timing of retraining, this is exactly the result from section 2, and with $\beta = 1$ we are back in the standard model.

Figure 2: The Unemployment Trap

Now consider agents with present-biased preferences, i.e. the case of $\beta < 1$. All future selves of these persons prefer to retrain if condition (12) holds. The analysis below focuses on the case where people are not aware of their time-inconsistency problem, i.e. they do not realize that their tastes change when they get closer to the moment when they originally intended to execute their retraining decision.\(^\text{10}\) Like the rational agents they postpone retraining. However,\(^\text{10}\) These persons are called naive agents in O’Donoghue and Rabin (1999). Sophisticated agents would realize their
in the last period of eligibility for unemployment benefits (at $t = \tau - 1$, when the rational agents retrain), the present-biased value of life-time income becomes

$$V_{\tau-1}(h, \tau) = b(1 - \theta)h - k_{\tau-1} \cdot c \cdot e + \beta \sum_{s=1}^{\tau-1} \delta^s (1 - \theta) \left[ (1 - d)h + \left( \sum_{i=0}^{\tau-1} k_i \cdot e \right) \right]$$  \hspace{1cm} (13)

implying that they will retrain if

$$c < \beta (1 - \tau) \tilde{\delta}_T.$$  \hspace{1cm} (14)

They will not retrain if the costs of retraining fulfill

$$\beta \tilde{\delta}_T < \frac{c}{1 - \theta} < \tilde{\delta}_T.$$  \hspace{1cm} (15)

If condition (15) holds, present-biased agents are not retrained when they lose eligibility for unemployment benefits although they originally planned to use the unemployment spell to upgrade their skills.

Figure 2 illustrates the consequences of a failed retraining episode depending on the worker’s initial skill level. Because retraining was, in principle, worthwhile, failed retraining shifts lifetime income $V(h, \tau)$ downwards. At the upper end of the education spectrum, between $h'_{C}$ and $h_{C}$, we find those workers who would have preferred to be employed had they known that they run into a time-inconsistency problem and do not take up the originally planned retraining. At intermediate education levels, between $h'_{A}$ and $h'_{C}$, present-biased preferences have no consequence on the unemployment decision (but, of course, on lifetime income). At the lower end of the education spectrum, between $h_{A}$ and $h'_{A}$, we observe the sad result that workers who originally planned to re-enter employment after a spell of unemployment used for retraining find themselves lacking the willpower to do so. Yet, with failed retraining and human capital erosion, their productivity is so low that living on the dole permanently is the best available option. Thus, they end up unintentionally as non-participants. Some of the well-educated are lured into unemployment, but will not remain on the dole permanently. It is the low-educated that fall prey to the unemployment trap and get stuck on the dole permanently.

The preceding discussion indicates the importance of active labor-market policies. If retraining capabilities are equally distributed across initial education levels, a sufficiently high subsidy of present-bias and thus execute retraining inefficiently early during the unemployment spell. Thus, sophisticated agents will not run into the unemployment trap as discussed here.
retraining costs (or a tax allowance) that drives $c/(1 - \theta)$ below $\beta \delta_T$ would eliminate the time-inconsistency problem according to the model. More generally, any commitment device that enforces retraining would be beneficial for the unemployed (in the sense of increasing their long-run utility) and would reduce short-run and long-run unemployment.

The expression “unemployment trap” usually refers to a situation where a jobless person is unable to increase his income through employment. This applies to all non-participants in our model. What we are concerned with here is the possibility that an agent ends up as NonPart against his best intentions. Note that the discussion above provides a rationale for an unemployment trap resulting from agents having present-biased preferences but are otherwise rational. Our account of an unemployment trap is not based on strategic interaction. In contrast, an unemployment trap may loom, for example, when multiple equilibria arise due to externalities from hiring restrictions (Saint-Paul 1995), due to discrimination of long-term unemployed (Acaroglu 1995), or from an interplay of social norms and voting on welfare policies (Lindbeck et al. 1999).

A further explanation for why people end up as non-participants, a status they would have chosen to avoid ex ante, is based on “forced unemployment”, which can easily be integrated into the model of section 2. Forced (short-term) unemployment occurs if a worker’s optimal choice, given the prevailing labor market conditions, is to work but the person is for some external reason inhibited from doing so and is therefore in fact unemployed. Forced unemployment increases the incidence of NonPart. The intuition for this result is as follows: Some workers with relatively low human capital endowment are only slightly better off by working than by not working. If these workers are forced to enter unemployment, their human capital degrades. If this degradation is pronounced enough and if human capital investments during unemployment are costly enough, their human capital erodes to the point where it does not pay to work again at the time when re-employment is possible.

6. Conclusion

This paper has offered a micro-economic tool for the unified analysis of unemployment and withdrawal from the labor force. Still simple enough to be solved analytically and discussed diagrammatically, the model has highlighted the importance of labor market institutions (generosity and duration of unemployment benefits, social assistance, taxes, and retraining costs)
and how they interact with personal characteristics (age, retraining costs, rate of human capital degradation) and stylized exogenous labor market fluctuations to explain the duration of the stay on the dole and retraining efforts. Our model provides a theoretical foundation for recent empirical studies who find institutional variables at the heart of the (un-) employment problem.

Despite our mostly intuitive results, which are in line with much empirical evidence, we would like to caution the reader to jump to policy conclusions for several reasons. First, any quantitative policy assessment would require to embed the model in a macroeconomic context and integrate it into a general equilibrium model of job search and matching. While this would possibly destroy the general solvability and beauty of the model, we expect little value added. This is because the micro-economic model already suggests that “it depends”. Therefore, the second and perhaps more important reason for caution is that the comparative statics have shown that the individual characteristics of the unemployed (education, skill loss, and age) determine the impact of institutional change. This holds in all cases with respect to the magnitude of effects and sometimes even with respect to their sign. As a consequence, the heterogeneity of the workforce must be taken into account when analyzing the implications of policy interventions.

Nevertheless, we believe some general conclusions follow from our model. We identify skill degradation as an important determinant of long-term unemployment as in Ljungqvist and Sargent (1998). In contrast to these authors, we do not find the problem to be aggravated by unemployment benefits. Higher unemployment benefits, while increasing short-term unemployment, can actually be favorable in the long-run because individuals may use a spell of short-term unemployment for retraining. Our analysis has determined generous social assistance, high tax rates, and macroeconomic labor market shocks as the main amplifiers of the impact of skill degradation effects and thus as the main culprits of the European unemployment problem. In addition, we identify – in line with the empirical evidence – low-skilled workers and older workers as particularly prone to human capital degradation and non-participation. Finally our analysis has emphasized the role of retraining costs and active labor market policies. These policies are particularly important when the unemployed have present-biased preferences and lack the willpower to retrain. In this case, voluntary short-term unemployment is like a slippery slope and results in a permanent life on the dole, against one’s best intentions.
Appendix: Comparative Statics without (short-term) Unemployment

If life-time incomes intersect in a way that UnEmp is never the best choice as in Figure 3, human capital endowment $h^B$ separates employment and non-participation. The relevant derivatives are

$$\frac{\partial h^B}{\partial b} = \frac{\delta_r h^B}{\delta_r (1-b) + \delta_T} > 0$$

$$\frac{\partial h^B}{\partial \tau} = \delta' \left( \lambda_0 - \lambda_r - \frac{s}{1-\theta} + h^B b \right) \frac{1}{\delta_r (1-b) + \delta_T}$$

$$\frac{\partial h^B}{\partial s} = \frac{\delta_T}{(1-\theta) \left[ \delta_r (1-b) + \delta_T \right]} > 0$$

$$\frac{\partial h^B}{\partial \theta} = \frac{\delta_T s}{(1-\theta)^2 \left[ \delta_r (1-b) + \delta_T \right]} > 0$$

$$\frac{\partial h^B}{\partial d} = \frac{\partial h^B}{\partial c} = 0$$

$$\frac{\partial h^B}{\partial \delta_T} = \left( \frac{s}{1-\theta} - h^B \right) \frac{1}{(1-\theta) \left[ \delta_r (1-b) + \delta_T \right]^2}$$

$$\frac{\partial h^B}{\partial \lambda_0} = \frac{\delta_r}{\delta_r (1-b) + \delta_T} > 0, \quad \frac{\partial h^B}{\partial \lambda_r} = \frac{\delta_T}{\delta_r (1-b) + \delta_T} > 0$$

In principle, the effects on employment and NonPart are the same as for the non-generate case discussed in the text. Sometimes, of course, there are no partial effects observable. Because the NonPart will never be at work again they are not affected by retraining costs and do not suffer from (further) increasing skill degradation. This is not the same as saying that there are no effects at all. The parameter variation can be so large that NonPart is affected because UnEmp turns out to be worthwhile and the degenerate case ceases to exist.

The sign of $\partial h^B / \partial \delta_T$ is undetermined and only unambiguously positive without current labor market frictions ($\lambda_0 = 0$). In this case NonPart is decreasing with $\delta_T$, i.e. younger workers are less afflicted with unemployment. The sign of $\partial h^B / \partial \tau$ is also ambiguous. It includes a degenerate case where longer eligibility for unemployment benefits leads to lower unemployment. In order to provide an intuition, we assume that labor market frictions are structural ($\lambda_0 = \lambda_r = \lambda$),
implying that the sign of the derivative equals the sign of

\[ b(1 - \theta)\lambda(\delta_r + \delta_T) - s(1 - b). \]

A degenerate case may occur if \( s \) is very high and \( b \) is low. Then, social assistance is so generously granted compared to unemployment benefits that increasing eligibility for unemployment benefits entails the dominating negative effect of delaying waiting time until eligibility for social assistance. Of course, without social assistance (\( s = 0 \)) this channel is always closed.

NonPart is independent from retraining costs and human capital degradation because the choice is between being never and always unemployed (\( \partial h^B / \partial d = \partial h^B / \partial c = 0 \)). The other derivatives are in line with the normal, non-degenerate case discussed in the main text: NonPart increases for higher unemployment benefits, higher social assistance, higher taxes rates, and higher labor market frictions.
