We are grateful for helpful comments from Pedro Martens, Ian Walker, and participants at: the annual conference of the Royal Economic Society, Warwick, March 2008; the annual conference of the American Economic Association, New Orleans, January 2008 and especially to the discussant, Tom Dee; the IFS/CEE/CEP seminar, November 2007; the Reading University economics seminar, October 2007; the Warwick economics department econometrics workshop, November 2006 and the European Summer Symposium in Labor Economics, Munich, September 2007.

## **Abstract**

We exploit a rich administrative panel data-set for cohorts of Economics students at a UK university in order to identify causal effects of class absence on student performance. We exploit the panel properties of the data to control for unobserved heterogeneity across students and hence for endogeneity between absence and academic performance of students stemming from the likely influence of effort and ability on both absence and performance. Our estimations also exploit features of the data such as the random assignment of students to classes and information on the timetable of classes, which provides potential instruments in our identification strategy. Among other results we find that there is a causal effect of absence on performance for students: missing class leads to poorer performance. There is evidence from a quantile regression specification that this is particularly true for better-performing students, consistent with our hypothesis that effects of absence on performance are likely to vary with factors such as student ability.

## 1. Introduction

The analysis of the factors associated with educational attainment and performance has been a major focus of work in the last decade as economists have attempted to obtain a deeper understanding of the processes associated with the acquisition of human capital. Work has tended to focus on the importance of factors such as class size and peer effects; see, for example, Hanushek *et al.*, (2003), Hoxby, (2000), Krueger (2000), Ehrenberg *et al.* (2001), and Burtless (1996), *inter alia*. Much of the work has concentrated on the educational attainment of pupils in compulsory schooling, with less attention paid to higher education. Yet the processes associated with post-compulsory human capital accumulation are internationally important given increasing participation rates and the economic significance of the higher education (HE) sector in modern economies.

A further motivation for analysing HE processes specifically is that their nature is likely to be fundamentally different to those characterising earlier-stage cognitive development, with greater student autonomy in study one obvious reason for this. One aspect of this autonomy is the relative freedom of students in HE to choose to absent themselves from class. More generally, the modes of study of HE students are less prescribed than in compulsory education: the responsibility for the efficient allocation of study time lies largely with the student – though this is not necessarily uniformly true across all university courses. Our work focuses on issues regarding the relationship between absence from class and academic performance of university students, a subject which has attracted attention since the influential paper of Romer (1993). Our analysis concentrates on variations across students in the causal impact of absence on performance.

Currently in the UK, as elsewhere, there are significant changes taking place in HE. Following several decades in which the unit of resource has fallen, the introduction of tuition

fees for home students offers the potential prospect of better resourced teaching in the UK. There are a number of possible implications for the ways in which the nature of the teaching and learning environment in universities might evolve. Traditionally, university teaching in the UK is based on large-group lectures and small-group classes. Attendance at lectures has been seen as optional. Class attendance, however, has been regarded as compulsory for various reasons, which include the perception that: (i) the value added in class is greater than that in lectures and students might not appreciate this and (ii) class attendance by each student has positive externalities for other students through the contributions each can make to the learning process. With declining resources, class sizes have been increasing across the HE sector and this has undermined the strength of both of these arguments. Indeed, it is likely that in large classes attendance imposes negative externalities through congestion effects.<sup>1</sup> There is a view in the sector that class teaching is no longer as effective as it was and that students, perceiving this, have higher absence rates. There are various responses to this, including: abandoning small group class teaching; resourcing it better; reforming it; making attendance compulsory; and/or creating more explicit incentives for attendance. Developing a better understanding of the effects of class attendance on student outcomes seems timely.

Our empirical analysis exploits a rich administrative panel dataset for cohorts of economics students at a UK university. We exploit the panel properties of the data to control for unobserved heterogeneity across students and hence for endogeneity between attendance and performance stemming from the likely influence of ability, effort, and motivation on both. That students are randomly assigned to classes avoids the potential endogeneity problems that occur when students can self select into classes. Finally, we use the idea that the time slot of the class in the weekly timetable produces exogenous variation in a student's

---

<sup>1</sup> Lazear (2001) develops a theoretical model in which classroom education has public good characteristics. In Lazear's model, a disruptive student reduces others' learning.

attendance and hence acts as a potential instrument with which to identify a causal effect of attendance on performance.

From our empirical analysis, we find, among other results, that there is a significant association between missing class and student performance, but that this effect is weakened – though remains significant – when controlling for unobserved individual effects. In a quantile regression specification, it emerges that the adverse effect of missing class is greater for better-performing students, consistent with the hypothesis that effects are likely to vary with factors such as student ability.

In the next section, we present a brief literature review. This is followed, in Section 3, by a theoretical motivation for the analysis of the relationship between absence and student performance. Section 4 presents the data, and key summary statistics, based on cohorts of economics students at the particular UK University. In Section 5 we describe the econometric model of the causal effects of tutorial absence on student performance and discuss the results. Section 6 concludes and offers further remarks.

## **2. Contextual literature**

Romer (1993) presented quantitative evidence on absenteeism and performance in economics courses at 3 universities in the US. Romer reported absenteeism to be ‘rampant’, with an overall absence rate of about one-third. Romer also reported evidence consistent with the hypothesis that absence is associated with poor student performance, while acknowledging that no causal effect had been demonstrated given the endogenous nature of the relationship between attendance and performance. The general assumption in the literature is that more able (and motivated and hard-working) students are more likely both to attend and to score highly in their courses. Thus, in the absence of adequate proxies for such personal characteristics, part of any estimated effect of attendance will reflect a form of (upward)

ability bias arising out of endogenous selection. Romer does include in his regression analysis controls for prior grade point average on the grounds that these will capture some of the otherwise unobserved heterogeneity across students. Indeed, Romer notes that as the estimated effect of prior performance depends in part on previous attendance, the inclusion of prior scores could cause a *downward* bias in the estimate of the effects of attendance on performance; part of the effect being captured in the control variable.

Following Romer (1993), Durden and Ellis (1995) analyse survey data on absences for 346 economics students on a principles of economics course at a single US university. They report that the average effect of absences on performance is modest, but that there are substantial adverse effects when absence exceeds certain threshold levels. Devadoss and Foltz (1996) also report significant positive effects of attendance on student performance from a survey-based analysis of students, across 4 US universities, taking a course in agricultural economics. The analysis exploits survey responses to questions eliciting information on prior attainment, student effort and motivation. This information generates proxies for these typically unobserved characteristics. Dobkin, Gil and Marion (2007) use a discontinuity design approach generated by a policy of making attendance compulsory only for students achieving below some threshold on a mid-term test in each of three large economics classes in a US university. They find that the policy had a significant effect on attendance and also generated a significant discontinuity in final examination performance.

It is important to note that the literature for the US typically measures attendance rates aggregated over all forms of meetings, lectures and smaller group meetings combined, and labels these as ‘classes’. There is, however, a potentially important distinction to be drawn between attendance at lectures – typically large group meetings – and at classes, which are typically small group meetings. In our own study, we are concerned with the causes and consequences of missing small group classes.

Rodgers (2002), using data on attendance in an introductory statistics course at an Australian university, finds a strong positive association between attendance at tutorials (small group classes) and performance but, comparing across cohorts, reports that the introduction of a scheme which raised attendance was not associated with enhanced performance. Rodgers infers that attendance alone does not improve achievement. Stanca (2006) uses a survey-based panel data set of students taking a microeconomics course at an Italian university. The analysis exploits the panel nature of the data to take account of unobserved characteristics correlated with attendance and produces estimates indicating a significant positive causal effect of attendance on performance: both class and lecture attendance rates are observed and have similar effects on performance.

Kirby and McElroy (2003), using travel-to-college commuting times as an instrument, find that attendance has a positive and diminishing marginal effect on grades achieved at an Irish university: they find that tutorial attendance has quantitatively bigger effects than lecture attendance. In contrast, for the UK, Martins and Walker (2006) find no significant effects of class attendance on performance for students in the Economics Department at a leading UK University, and also find no significant effects of smaller classes on improved performance. Dolton, Marcenaro and Navarro (2003), exploiting rare information on time use for students at a Spanish university, find that both formal attendance and self-study activity are significant positive determinants of examination score: formal attendance includes both class and lectures, the two are not distinguished.

In our own work, we focus exclusively on absence from small group classes as we do not have information on lecture absences: attendance at lectures is regarded as voluntary and is not monitored. Comprehensive lecture notes are typically available on-line and are to some extent substitutable by recommended textbooks. Hence missing lectures is, *a priori*, likely to

be less costly than missing small group classes, where teaching is more targeted to the individual's needs and is less easily substituted by other forms of study.

Our analysis attempts to uncover causal effects of small group class attendance (or, more specifically, absence – its converse) on the performance of students taking core courses in the second (intermediate) year<sup>2</sup> of an economics degree course at a UK university. We exploit administrative data for 3 cohorts of students and for 3 common compulsory courses for each student. Given the panel nature of the data we are able to control for unobserved heterogeneity. We also control for previous attainment and use precise information on the students' class timetables to generate instruments which we employ in a strategy for the identification of causal effects.

### 3. Theoretical discussion

Consider an educational production function<sup>3</sup> of the following form:

$$p = p(c, q, r), \tag{1}$$

where  $p$  is a measure of a student's educational performance,  $c$  is the amount of time allocated by the student to attending class,  $q$  is the amount of time spent in alternative forms of study activity, and  $r$  captures personal characteristics such as ability, effort and motivation.

Suppose that the objective function of the student is to maximise performance, given by equation (1). Among the constraints will be a time constraint of the form:

$$c + q \leq \bar{t}, \tag{2}$$

---

<sup>2</sup> We describe the choice and the properties of the data and of the institutional context in more detail in the Section 4.

<sup>3</sup> For a discussion of the estimation of production functions for cognitive achievement, see Todd and Wolpin (2003).

where  $\bar{t}$  is the maximum amount of time available for study in a given period. In the production function, assume initially that  $c$  and  $q$  are neither complements nor substitutes but are independent. The problem for the ‘grade’-maximising student is to allocate their time efficiently between attending class and alternative study time uses, such as attending large-group lectures, private study, or completing assignments. Privately efficient time allocation – we are ignoring externality and public good characteristics of classroom attendance for now (see Lazear, 2001) – will require the student to have knowledge of the marginal productivity of  $c$  and  $q$  in (1).

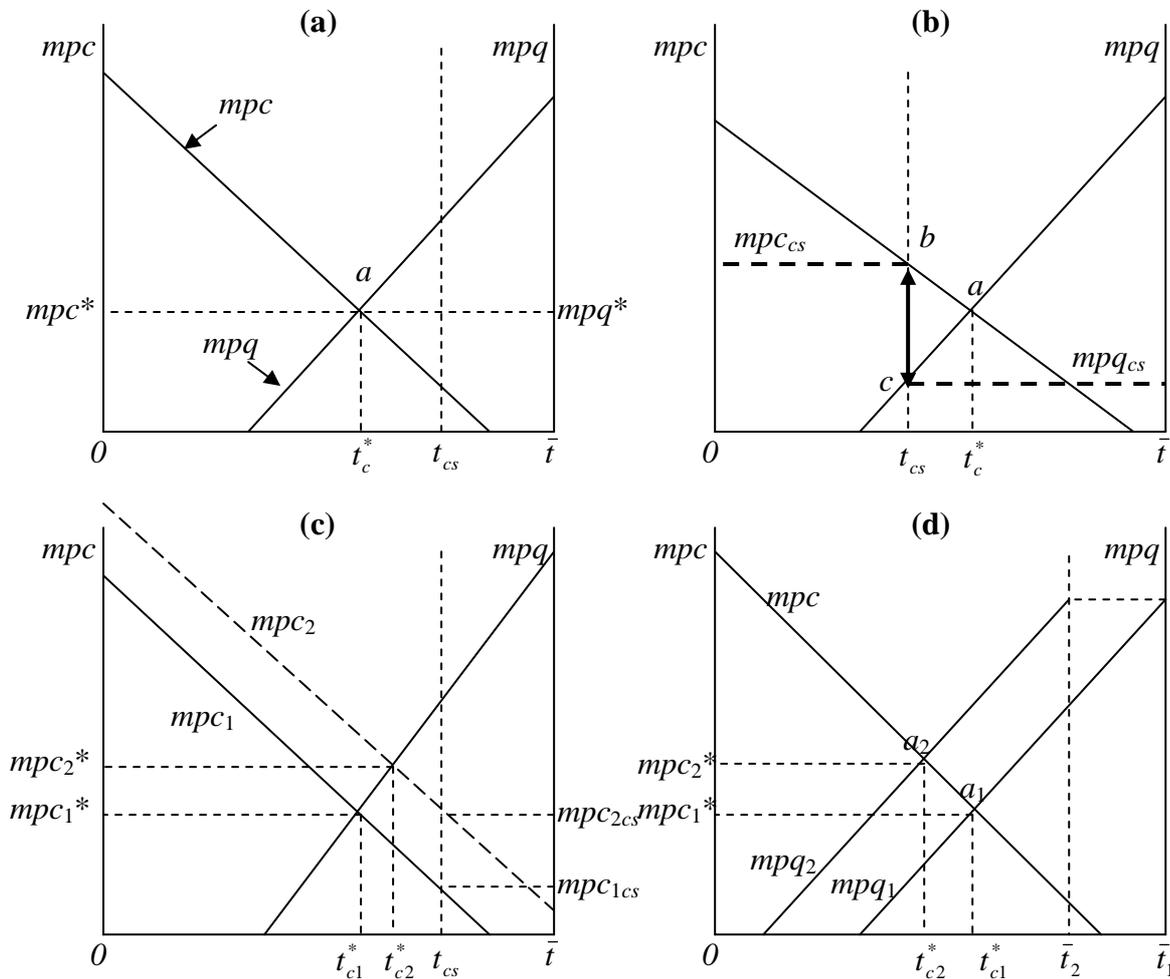

In reality, marginal products are likely to be person-specific: one of the challenges for the student is to reflect on their own learning strategies and capacities in developing for themselves a mature appreciation of ‘what works best for them’ – that is, of their own marginal productivities for the factors in their educational production function. Implicitly, the importance of this is embodied in the current emphasis on ‘reflective learning’ and ‘personal development planning’ in UK HE. One of the reasons for not selecting first year students in our data analysis is the acknowledgement that only by the second year will students have had sufficient experience of HE to be able to make informed judgements about their optimal learning strategies. This is also recognised by most UK universities as, typically, first year performance does not contribute to final degree marks and classifications.

Assume for now that the student has accurate information regarding the parameters of their own educational production function. Assume also that marginal products of study time are positive but diminishing in each study activity and are independent of each other and of

ability, i.e.  $\frac{\partial p}{\partial c} \equiv mpc > 0$ ,  $\frac{\partial p}{\partial q} \equiv mpq > 0$ ,  $\frac{\partial^2 p}{\partial c^2} < 0$ ,  $\frac{\partial^2 p}{\partial q^2} < 0$ ,  $\frac{\partial^2 p}{\partial c \partial q} = 0$ ,  $\frac{\partial^2 p}{\partial c \partial r} = 0$ , and

$\frac{\partial^2 p}{\partial q \partial r} = 0$ . We additionally assume that,  $\frac{\partial p}{\partial r} > 0$ . Some of these assumptions will be relaxed

later. With these assumptions, we can represent diagrammatically the solution to the problem defined in equations (1) and (2) for the grade-maximising student: see Figure 1a.

**Figure 1 - Efficient study-time allocation.**

From Figure 1a, we can see that the grade-maximising student will optimise at point  $a$ , choosing to attend  $t_c^*$  hours of class and engaging in  $\bar{t} - t_c^*$  hours of additional study. Whether this involves absences from class will depend on the number of scheduled classes available to the student. If there are significant external net benefits of attending class, then – depending on institutional resources – the number of classes supplied to the student, denoted by  $t_{cs}$ , is more likely to exceed the student’s optimal number, and hence  $t_{cs} > t_c^*$ , as in Figure

1a. If, on the other hand,  $t_{cs} < t_c^*$ , then the outcome will be inefficient, at least according to the student's private calculus: as shown in Figure 1b, where there is now a wedge between the marginal products:  $mpc > mpq$ .

In the case described in Figure 1a, the optimising student will choose to miss  $t_{cs} - t_c^*$  hours of class. At the margin, were the student required to attend all  $t_{cs}$  classes, then there would be a fall in the student's performance level as  $mpq > mpc$  for the marginal classes. Suppose that class attendance is compulsory but that absence is not penalised. Then the propensity of students to miss at least some fraction of the sub-optimal  $t_{cs} - t_c^*$  classes will depend on their attitudes to compliance. Suppose that this is randomly distributed across students. Then it follows that, under the assumptions of the model, in a learning environment in which class attendance is regarded as compulsory but in which, without enforcement, some individuals absent themselves nonetheless, class absences in the range  $t_{cs} - t_c^*$  will be associated with improved performance. This is the opposite prediction to the standard hypothesis in the literature that predicts that absence will affect performance adversely. Our prediction arises from an optimising framework in which choices are made with perfect information: at the margin, attendance is productive, but only up to the optimising point.

So far, we have assumed that factor inputs are independent. But suppose now that, *ceteris paribus*, the marginal product of attending class is positively correlated with ability: that is,  $\frac{\partial^2 p}{\partial c \partial r} > 0$ . This case is represented in Figure 1c, where the  $mpc$  for more able students,  $mpc_2$ , lies above that of the less able,  $mpc_1$ . The result is that the more able students will optimally choose to miss fewer classes:  $t_{c2}^* > t_{c1}^*$  in Figure 1c. In an environment in which class attendance is voluntary, performance will be greater for the more able students and, hence, will be negatively associated with absence from class. Of course,  $mpq$  may also

be positively correlated with characteristics captured by  $r$ . In this case, the relative sign of  $t_{c2}^* - t_{c1}^*$  (and hence the association between performance and absence) will be ambiguous: it will depend on comparative advantage; that is, the relative correlation of  $r$  with  $mpc$  and with  $mpq$ .

In an econometric estimation of the effects of absence on performance, correlation between  $r$  and either of the other arguments –  $c$ ,  $q$  – in the education production function given by equation (1) could potentially generate endogeneity bias if  $r$  is not perfectly observed. If more able students are less likely to be absent from class –  $t_{c2}^* > t_{c1}^*$ , as in Figure 1c above – then the estimated adverse effect of absence on performance will be biased upwards, in absolute terms, through endogenous selection and the resulting ability bias. The empirical investigation of the effects of absence from class on performance should be constructed so as to allow for heterogeneous effects of this sort. This observation lies behind the design of our later estimation strategy. In the case in which  $t_{c2}^* < t_{c1}^*$ , then the direction of endogeneity bias will be downward – but, again, the effects will be heterogeneous.

As we have seen, ability differences across students can affect absences from class through their influence on the educational production function, equation (1). But suppose now that there are differences across students in the time endowment for study,  $\bar{t}$ . In Figure 1d, we consider the effects of an exogenous reduction in the amount of time available for study activity:  $\bar{t}$  falls from  $\bar{t}_1$  to  $\bar{t}_2$ . In this case, there will be an increase in the number of classes missed (assuming  $t_{cs} - t_{c1}^*$ ) together with an associated reduction in performance. In the model, the total time endowment for study,  $\bar{t}$ , is taken as exogenous. In reality,  $\bar{t}$  is likely to be influenced by various arguments. For example, students from economically less advantaged backgrounds may be more likely to have to engage in part-time labour market activity, thereby reducing  $\bar{t}$ . The study time constraint may also be related to student ability,

and hence to  $r$  in equation (1). If, for example, more able students undertake more non-curricular activities, then  $\bar{t}$  will be negatively correlated with ability. In this case, more able students will be more likely to miss class. Note also from Figure 1d that the effect of missing class will be greater for more able students as  $mpc_2^* > mpc_1^*$ . Again, unobserved differences in ability across students will generate a bias in the estimate of the effect of absence on performance as part of the association between absence and performance is being explained by a differential propensity of the more able to be absent from class.

In summary, we have seen that, in an optimising framework, the theoretical effect of absence on performance is ambiguous. If class attendance is compulsory and students differ only in a randomly-distributed propensity toward compliance, then absence will have a positive association with performance as the less compliant will be more likely to adhere to the optimal number of classes. If, on the other hand, students are heterogeneous in ability then they will be likely to choose different optimal levels of class attendance: if ability is associated with a comparative advantage in class attendance – as in Figure 1c – then the more able will have a higher attendance rate and absence will be associated with poorer educational performance. Ability might also be correlated with the study time endowment: if more able students have a higher opportunity cost of studying, then it is likely that they will attend fewer classes. In this case, absence will be likely to have a positive association with performance. Estimation of the effects of absence on performance will be biased if ability is not observed or accurately proxied: the direction of bias will depend on the relative dominance of factors of the type we have identified. Finally, the model predicts that the magnitude of any effects of absence on performance will vary with student ability: if, for example, ability is relatively highly correlated with productivity of class attendance then the negative effect of any given level of absence on performance will be most pronounced for the more able students. These considerations inform our choice of empirical estimation strategy.

The model we have outlined so far assumes that students have sufficient information to be able to select their optimal level of class attendance. In reality, this is unlikely and students will make mistakes, attending either more or fewer classes than would be privately efficient. If students systematically under-estimate the marginal product of class attendance, then absence will tend to have an adverse effect on performance. This tendency might also be correlated with ability, so that less able students miss more classes and suffer a further reduced level of performance.

Informed by this contextual optimising framework, our empirical strategy will involve: first, an analysis of the factors associated with being absent from class; second, a simple, or ‘naïve’, analysis of the association between student performance and student absence from class; third, an attempt to identify causal effects of absence from class on student performance; and fourth, an investigation of whether or how any effects vary systematically with student characteristics, such as those associated with ability. The following sections describe the data and the econometric strategy for investigating these and related issues.

#### **4. Data description and summary statistics**

This paper uses administrative data from the department of economics at a UK university, collected over a three year period, in order to investigate the association between absence from class and student performance. The observations are based on 444 2<sup>nd</sup> year undergraduate students admitted to the economics department to commence their 3-year degree in October of 2003, 2004 or 2005; the number of students in each of the three cohorts was 134, 159 and 151, respectively.

## 4.1 Institutional context

As is typical in the UK, students observed in the study graduate at the end of their third year with a degree which is classified into one of four main classes. This overall degree classification of students depends on their performance in the 8 courses which they take over the course of their 2<sup>nd</sup> and 3<sup>rd</sup> years of study, with the four courses taken in the 2<sup>nd</sup> year having the same weight as the four taken in the 3<sup>rd</sup> year. The 1<sup>st</sup> year is simply a pass/fail year determining whether students progress into their 2<sup>nd</sup> year of study. We focus exclusively on 2<sup>nd</sup> year students in this paper for two reasons. First, we wish to analyse the behaviour of students whose motivation is likely to be to maximise their final score in each course and as the 1<sup>st</sup> year is simply a pass/fail year, this may well not be the case: arguably, first year students are more likely to satisfy than to maximise. Second, we do not include 3<sup>rd</sup> year students in the analysis as these students self-select into optional courses for three of their four modules, creating potential problems associated with endogenous selection as well as an unbalanced panel.

Each of the 444 second year students observed in the study registers for three compulsory core courses (in microeconomics, macroeconomics, and econometrics) and for one optional course (selected from a potentially long list of courses from either economics or other social science disciplines). Our analysis is based on data relating only to the three compulsory courses: this gives us a balanced panel based on a total of 1332 observations.

In each course, each student is allocated to a tutorial class. These are small groups which meet with an academic tutor to complement lectures and which focus on an exercise sheet or discussion sheet given out by the lecturer of the particular course. Classes are provided for all compulsory 2<sup>nd</sup> year courses and attendance is regarded as compulsory. Students are allocated to their classes by the department and this is chiefly done on an

alphabetical basis. Classes meet every week in the econometrics course (a total of 20 classes in the academic year), but are held less frequently in macroeconomics (13 classes) and in microeconomics (16 classes). In each class, the tutor takes a register for that class and this information is recorded electronically. The students are sent warnings about each of their absences with reminders about the adverse consequences associated with a poor attendance record. A 3<sup>rd</sup> absence in any one course requires the student to see their personal tutor and a 4<sup>th</sup> absence means the student must discuss their behaviour with the programme director. After the 4<sup>th</sup> absence the student is put on report and a record of their attendance across all of their courses is monitored closely. The department can impose various penalties on students with poor attendance records and, in particularly bad cases, can seek to have a student's registration withdrawn from the University for persistent non-attendance at tutorial classes, although this did not happen over the period under analysis.<sup>4</sup> For this system of monitoring and punishment of absence to be effective, it is important that tutors enter accurate information on each student's class attendance. This is fully understood in the department and is itself carefully monitored and policed.

Once students have been randomly allocated to classes in each of their three compulsory courses, they are not free to re-allocate themselves to different classes – for example at times they might prefer or into groups with self chosen class mates. One reason for this is that classes are of fixed sizes and so re-adjustment would disturb the general equilibrium allocation. There is a process by which students can appeal to be re-allocated to a different class, but permission is granted only where a special case can be made, for example on the grounds of a timetable clash involving an optional module in a different department. If in any one week a student is unable to attend their allocated class, then they can attend an

---

<sup>4</sup> A further reason for restricting our analysis to compulsory courses is that attendance in optional courses is not necessarily recorded.

alternative class on a one-off basis. This would not be recorded as an absence. The key point is that assignment to class is a random outcome: we present evidence relating to this in section 5 of the paper. We note also that the attendance database distinguishes between condoned absences – due to, for example, illness or having to attend an internship interview – and uncondoned absences. In our empirical analysis we consider both types separately but find that the results do not vary across the two types, hence we combine the cases.

Student performance in each of the observed courses is examined by a 3-hour end-of-year written examination worth 80% and by two pieces of assessed work, each worth 10%. When we analyse student performance, we consider both overall performance and examination performance only. *A priori*, there is no reason to suppose that class attendance should affect one type of assessment more than another.

Among other information on each student, we observe: prior performance of each student in each of their first year courses; both the absence record and the performance of each student in each of the three compulsory 2<sup>nd</sup> year courses; gender; home (UK/EU) or overseas student status; entry cohort (2003, 2004 or 2005); the class to which they are allocated on each course; the time of day and the day of the week of the class; and the average student rating of the tutor in each class. Students are registered either for a single degree programme in economics or for a joint degree. Joint degree students take parallel courses to those for single economics students. In our econometric analyses, we control for this with the use of dummy variables. We have also re-estimated our econometric models on the basis of single degree students only and find that the results are robust to this: we prefer to include both sets of students as this generates a larger sample and improves the precision of estimates.

Historically, students in the department self-selected into their tutorial class groups through sign-up sheets on a first-come first-served basis in the micro and macroeconomics

courses. In econometrics, students were allocated to classes on the basis of their first year performance in statistics. Neither of these allocation methods generated random assignment. Since 2003, students have been allocated to their classes – in all compulsory 2<sup>nd</sup> year courses – by the Department administrators on the basis of the alphabetical ordering of family names.<sup>5</sup> Thus, combined with the collection of accurate data on absence, this provides the opportunity to exploit features of the data which have the characteristics of randomised experiments.

As we discuss in more detail in the description of our empirical methodology in section 5 below, the panel nature of our dataset enables us to control for unobserved heterogeneity: under the maintained assumption that unobserved individual-specific effects on performance are constant across courses. Randomised class assignment overcomes a number of possible sources of endogeneity between absence and performance – though not all sources. We are, however, able to use information on aspects of the assignment to class – such as by time of day – to construct instruments for the identification of causal effects of absence on performance.

## **4.2 Summary Statistics**

Despite being compulsory, attendance falls well short of 100%. Figure 2 plots the cumulative distribution function for the proportion of total absences across the three core courses for our 444 second-year students. From the figure, we note that the median person missed around 8% of their tutorial classes, while the 75<sup>th</sup> percentile student missed around 16% of classes. The mean level of absences, at 11%, is higher than the median, reflecting the fact that a small proportion of students missed a relatively large proportion of their classes, as

---

<sup>5</sup> We discuss below the extent to which this generates a random assignment of students to classes.

is evident from the figure. Surprisingly, approximately 12% of students missed no classes. Absence is clearly less rampant than in the case reported by Romer (1993) in his US study.

While Figure 2 is based on the absence rate observed for each of the 444 students over their 3 modules, Figure 3 is based on the tutorial group as the unit of observation, the figure showing the cumulative distribution of absences across the 142 groups.<sup>6</sup> For simplicity of exposition, consider the case of a hypothetical group with 10 assigned students and 20 meetings over the year: a group absence rate of 10% could arise from just one student missing all their class meetings or from each student missing 2 classes over the year, or from various combinations between these extremes.<sup>7</sup> An absence rate of zero for any one group means that no student was absent for any of the meetings of that group during the whole year: remarkably, almost 4% of groups had a zero absence rate. The median class experienced an absence rate of 10% while 25% of classes had an absence rate of 7% or less and 75% had an absence rate no higher than 15%.

Table 1 presents summary statistics of the variables used in the analysis, for the 444 students across their three core courses, broken down into bands according to the proportions of total class absences in each course: the band categories are defined as; (0-4]%, (4-8%], (8-15%], and over 15%.<sup>8</sup> Of the 2<sup>nd</sup> year students, 34% are female and 32% are overseas fee-paying. From the table, females are less likely to have high absence rates; overseas students appear to have higher rates of absence than do home students. The pattern of absences is not constant over the three cohorts: for example, the incidence of very low absences is disproportionately low among the 04/05 cohort. Table 1 shows that, in the raw data, there is a monotonic relationship between performance and absence in the second year: while the

---

<sup>6</sup> With 144 groups over the 3 modules, this equates to an average of about 47 groups per module and hence to an average of about 10 (of the 444) students per group.

<sup>7</sup> In the current paper, we do not exploit information on the distribution of absences by class by week.

<sup>8</sup> The bin values used on the percentage of absences ensure approximately equal numbers of observations in each bin.

average score across all students over their three compulsory modules is 60%, the average for students with fewer than 4% absences is 65% while that for students with more than 15% absences is 55%. Of course, this does not amount to evidence of a causal effect of absence on performance; we also see from the table that there is a monotonic relationship between absence and prior performance. For example, while the average 1<sup>st</sup> year maths score is 68%, it was 73% for students subsequently missing less than 4% of their 2<sup>nd</sup> year classes and 63% for those missing more than 15%. Similar monotonic patterns are observed between 2<sup>nd</sup> yr absence and (i) 1<sup>st</sup> year scores in statistics, (ii) the average score over all other 1<sup>st</sup> year modules, and (iii) having failed and re-sat 1<sup>st</sup> year modules. One might have expected students failing 1<sup>st</sup> year modules to have a better than average attendance record in the 2<sup>nd</sup> year: our discussion in section 3, however, shows that in an optimising framework, this need not follow.

Table 2 shows summary statistics behind which the unit of observation is at the level of the 142 tutorial class groups. The table also shows a breakdown by absence band, where the cut-offs are selected to generate approximately equal numbers of cases per band. The mean proportion of absences across the groups is 11% - close to the median reported from Figure 3. 13% of classes were timetabled at 9am. We can see an association between the absence rate from classes and the time at which they are timetabled. Among classes with the lowest absence rates, 11% of classes began at 9am: in contrast, 17% of classes with an absence rate in excess of 15% began at 9am. As we discuss in section 4, both time of day and day of week are potential instruments to use in our identification strategy. The timetable of classes is constructed around the constraints imposed by the timetable for lectures – which are not necessarily distributed uniformly across the week and hence there is likely to be clustering of tutorial classes by time and day. As teaching is typically not scheduled on a Wednesday afternoon (in order to accommodate sports activities), there are 9 morning or

afternoon sessions per week: random timetabling of classes would then generate 11% of classes on a Wednesday and 22% on each of the other days. Instead, because of clustering, as many as 38% of tutorials are on a Thursday and 16% are on a Wednesday. A disproportionately high fraction of tutorials with the highest absence rates occur on a Thursday, suggesting a binding timetable constraint for students on this day. In the current paper, we do not address the nature of this or other time constraints. Only 29% of classes occur in the afternoons: there is some evidence of a relationship between afternoon meetings and absence in the raw data: a relatively small proportion of classes with high absence rates are held in the afternoon.

A further tutorial characteristic concerns the students' reported evaluations of their tutors. At points during the academic year – prior to the final examinations – students record their subjective evaluations of the quality of their tutors' teaching on a scale of 1-5, where 1 is excellent and 5 is poor. The average mark for the tutor across all of their students on the 2<sup>nd</sup> year courses is 1.98. There appears to be no clear pattern between absences and tutor score in the raw data.

Figure 4 plots the distribution of 2<sup>nd</sup> year performance in the core courses for those students who missed no classes and also for those who missed at least one class. We note that not only is the distribution of marks shifted towards the left for those students who missed at least one class, but the shape of the distribution is also different. These are raw data plots; we turn next to multivariate analysis to account for the effect of absenteeism on the location and shape of the students' performance distribution.

## **5. Econometric Model and Results**

The data enable us to observe the performance and tutorial absence of students in each of their three compulsory 2<sup>nd</sup> year courses. With 444 students over three cohorts in each course,

we have a panel of 1332 observations. The dependent variable  $p$  in our model is the student's end-of-year performance measured as a score out of 100 for each of the student's three core 2<sup>nd</sup> year courses. The main explanatory variable of interest is the proportion of tutorial classes missed during the second year of study, called *absence*,  $a$ , defined with respect to each of the three core courses.

As discussed in section 3, performance is likely to be affected by factors such as ability, effort and motivation. These variables are unobserved in our dataset and nor do we have reliable proxies for them: we do include a variable for prior academic performance in our analysis, but do not claim that this is a good proxy for ability, partly because it is itself an outcome measure and not purely an input. That factors such as ability are not observed creates the potential problem of an omitted variable bias in the estimation of the effect of absence on performance as ability, *inter alia*, is likely to be correlated with absence. For example, in relation to Figure 1 (c), we hypothesized that higher ability students might have a higher marginal productivity of class attendance and hence have fewer optimal absences. In this case, OLS would generate an over-estimate of the effect of absence on performance.

In order to explore the above heterogeneities, we use the quantile regression (QR) framework.<sup>9</sup> Unlike the conventional least squares framework that looks at the effect on the conditional mean, the QR framework allows for differing effects of  $a$  on different parts of the  $p$  distribution, thus enabling us to look at the effect of  $a$  on the location, scale and shape of the  $p$  distribution. This is consistent with the theoretical discussions provided in Section 3, where the personal characteristic is allowed to interact in a non-trivial way with  $a$  and other covariates to have an effect on  $p$ .

---

<sup>9</sup> For a comprehensive introduction to the topic, see Koenker (2005).

The next econometric issue we have to address is how to estimate the causal effect of absences on performance. We have two potential problems of endogeneity bias: (i) ‘Class selection’ bias arising if students can choose their tutorial class, i.e. self-select into the most preferred time slot; (ii) ‘Ability/motivation/effort’ bias arising if, say, more able students are both less likely to be absent from class and more likely to perform well. We use the fact that the students are randomly allocated to classes where some of the class-timings are unpopular, to address the bias arising from (i). We could minimise (ii) with good proxies for ability (Romer, 1993). We have information on first year performance and we do include this in the model. However, this may not necessarily be a good measure of ability. Hence in absence of good measures of ability, we implement a novel two step procedure. We estimate the unobserved characteristic from a reduced form equation for absences using the panel nature of our data and use this estimated variable in the QR equation in the second step. Prior to discussing the details of the procedure, we provide some information of the instruments we use to identify the causal effect of absences on performance.

**Instruments:** The instruments we use are the days of the week and the actual time slot of the tutorial classes. These timings are centrally fixed and extremely difficult to change due to various constraints. Some of the times the classes are scheduled to take place are very unpopular times with the students. For example, the 9 ‘o’ clock class on a Wednesday morning. We create different indicator variables to pick up these effects and use them in the reduced form equation for  $a$ .

**Model:** The  $\tau^{\text{th}}$  ( $0 < \tau < 1$ ) conditional quantile of the  $p$  distribution for the  $j$ -th course,  $j = 1, 2, 3$ , for the  $i$ -th individual ( $i = 1, \dots, 444$ ) is specified as:

$$Q_{\tau}(p_{ij} | \mathbf{x}_{ij}, a_{ij}, v_i) = \beta_0(\tau) + \mathbf{x}_{ij}' \boldsymbol{\beta}(\tau) + a_{ij} \gamma(\tau) + v_i \delta(\tau) \quad (3)$$

where  $v_i$  is an unobservable individual characteristic. Note  $v_i$  can be correlated with other covariates in equation (3). The full set of additional controls used is discussed in the results section.

In linear panel data models, the unobserved  $v_i$  would be eliminated via the within group transformation prior to the application of OLS. However, this procedure is not open to us in the QR framework. We exploit the panel nature of our dataset to estimate the unobservable  $v_i$  from a reduced form equation for absences and use the estimated  $v_i$  in place of unobserved  $v_i$  in (3) in order to account for correlation between absences and unobservables. We use the timetabling characteristics of class meetings as instruments for the identification of the causal effect of absence on performance. We have described in section 4 how allocation to class is based on random assignment. The implicit assumption we are making is that class meeting times are likely to affect the absence choice of students but have no direct effect on performance once conditioned on absences. The details of the procedure used is summarized below.

### *Step 1*

We have absenteeism information on the three core courses for each individual  $i$ . Let  $a_{ij}$  be the proportion of tutorials missed by individual  $i$  in course  $j$ , where:

$$a_{ij} = z_{ij}\boldsymbol{\delta} + v_i + u_{ij} \tag{4}$$

$v_i$  is individual specific unobservable random effect which is assumed to have the same effect on all core courses.  $z_{ij}$  is a vector of covariates which includes our instrument which is the timings of classes. As discussed previously, students are randomly allocated to classes for which are largely centrally timetabled to avoid timetable clashes.

The observed  $a_{ij}$  generally lie between 0 and 0.69 with about 32% of the tutorials having zero absences and most of the students missing only up to about a third of the

tutorials. Given the nature of our dependent variable  $a$ , we estimate the model as a Panel Tobit model. As detailed in the Appendix, using this model, we obtain an estimate of  $v$  for each individual ( $\hat{v}_i$ ) which is known as the empirical Bayes predictions or shrinkage estimate (Goldstein, 2003). We use `gllamm` (2004) to obtain our estimates.<sup>10</sup>

### ***Step 2***

We use the  $\hat{v}_i$  in place of  $v_i$  in equation (3). Stata 9 was used to estimate the coefficients of our QR model. The standard errors were calculated by the bootstrap method using 500 replications which accounts for clustering at the individual level.

### **5.1 Results for Step 1: model of absenteeism**

Table 3, reports the results of the random effects Tobit model based on the absenteeism variable,  $a$ . The results suggest that students who performed well in their 1<sup>st</sup> year Statistics course tend to have lower absenteeism in their 2<sup>nd</sup> year. There are some interesting findings in terms of the information we have on the time of the tutorial class. We find that tutorial absence is markedly higher for the 9am class and to a lesser extent for all mornings classes (those starting before midday) compared to afternoon classes. Relative to Thursday classes, there are significantly higher absences in Wednesday classes. Monday, Tuesday and Friday classes attract more attendance compared to Thursday classes. We note that lower absence is associated with a lower tutor score that is, with a more favourable evaluation.

On personal characteristics, we find that female students miss fewer classes than do male students. Overseas students are found to miss more classes compared to home (EU) students, holding all else constant. Absence was higher in 04/05 than for the other two later

---

<sup>10</sup> Results from a model where we use a random-effects ordered probit for the first stage in order to estimate the unobserved individual specific term produced very similar results and therefore not reported here. We also used a generalisation of the two-step method proposed by Buchinsky (1998, 2001) and included the generalised residual and its square from the first stage model estimates in the second stage quantile regression model. The results are not reported here since they were very similar to the results reported here.

cohorts. Attendance at classes differs significantly only for one of the subjects, with Econometrics experiencing markedly greater absenteeism.

The variance of the individual-specific random effects is found to be significantly different from zero. A plot of the Bayesian estimate of the random effects  $\hat{v}_i$  is given in Figure 5a. As expected, it is unimodal and centred around 0. Figure 5b plots the estimated random effects but now separately for students who had no absences in a particular course and for those who had at least one absence in a particular course. Interestingly, the density plot is shifted towards the negative part for those students who had no absences. This implies that these students have a characteristic which makes them less prone to absenteeism.

## 5.2 Results for models of performance

We consider two empirical models: (1) the benchmark models treating absenteeism as exogenous (Table 4 panel 1 results), and (2) the models treating absenteeism as endogenous using the estimated unobserved individual-specific term as a control for endogeneity in the performance equation (Table 4 panel 2 results). When we discuss these two empirical models, we present results from pooled ordinary least squares estimation (OLS) (Column [1]), Within Group Estimation (WG) (Column [2] in panel 1) and Instrumental Variable Estimation (using the predicted absences from the first stage panel Tobit model – Column [2] in panel 2) and Quantile Regression estimation (QR) (Columns [3] to [11]). The estimated effects of absences along with the 95% confidence intervals from the within group estimation and also the quantile regression models are presented in Figures 6A and 6B.

Prior to discussing the results from various estimations, we summarise what the various estimates may be telling us. Assuming that there is no heterogeneity in the effects of covariates on performance, OLS would consistently estimate the penalty attached to missing classes on the conditional mean performance if there are no selection effects and there is no

unobserved heterogeneity. On the other hand, if there is selection and if this selection can be adequately captured by allowing for the unobserved individual effect, WG estimation would provide consistent estimators. Now, turning to the QR model results, these models allow for a heterogeneous effect of the covariates on the various parts of the performance distribution.

We first discuss the results from Model 1, the models that treat absenteeism as exogenous, presented in Table 4 panel 1. A cursory examination of the plot in Figure 6A suggests the presence of some heterogeneity in the effects of absences on performance. The penalty attached to missing classes is generally found to be smaller for high ability students. It is estimated that for students in the top 10% of the performance distribution being absent from 10% of classes is associated with around a 1 percentage point loss in the subject score, *ceteris paribus*, compared to about 2 percentage points for those students in the bottom 10% of the performance distribution. Interestingly, the penalty for missing classes is very much smaller on the conditional mean performance from the within group estimation. Also, we note that the OLS estimate is very similar to the estimate from the QR model at the median. Therefore, we conclude that there might be some effect of unobserved individual characteristics that needs to be accounted for. Comparison of WG with that of the QR model results indicates that not only might controls for unobservables be relevant, but also that some allowance for heterogeneous effects of covariates on different parts of the performance distribution is important.

Results for other variables included in the model are also informative. We find that females perform worse than males and that this negative effect is increasing across the quantile index. While this result might be viewed as surprising, McNabb *et. al.* (2002) find that while, on average, females perform better than males at University, they are significantly less likely to obtain a first class degree than males. Given that the criteria for admission into

the Department of Economics is AAB at A-level (or equivalent),<sup>11</sup> we are by definition observing already high performing individuals.

The coefficients on variables reflecting 1<sup>st</sup> year performance are as expected, although, in general, these do not show much variation across the quantiles. More interestingly, we find that the effect of the tutor score variable is negative, with students performing better in classes where the tutor has a lower score (better evaluation), although this negative effect becomes smaller across the quantile index.

We next turn to the models that allow for the possibility of endogenous selection in the number of classes the student chooses to attend, presented in Table 4 panel 2. The IV results (Column [2]) are very similar to the OLS results reported in panel 1 (Column [1]), with exogenous absenteeism, where being absent from 10% of classes is associated with around a 1.6 percentage point loss in the subject score, *ceteris paribus*. For the models presented in Columns [1], and Columns [3]-[11] an estimated ‘individual specific characteristic’ variable is included, although this variable is only significant in the bottom half of the distribution. While the coefficient estimates on most of the covariates are again very similar in terms of magnitude and significance to those reported in panel 1, the coefficient estimates on the absence variable are markedly reduced. Interestingly, we now find that the effect of missing classes is estimated to be significant only for high ‘ability’ students. Missing 10% of classes is estimated to be associated with around 1-2 marks for this group of students. The estimated effect of missing class for the low ‘ability’ students is insignificantly different from zero when selection is accounted for in the estimation.

In summary, when we take into account that individuals might be self-selecting to miss class, we find there is a penalty attached to absence - but only for more able students.

---

<sup>11</sup> A-levels are graded A through to E, with A being the top grade.

The fact that the estimated effects of absence on performance are less negative in the endogenous than in the exogenous model is consistent with our theoretical discussion of Figure 1c where we predicted a negative ability bias – and hence that ability disproportionately raises the marginal product of class attendance, relative to its effect on the marginal product of other forms of study. That the average effect of absence on performance is still negative in the endogenous model suggests that there is no particular excess supply of classes: this is evidence against the case presented in Figure 1a, in which the causal effect of absence on performance would be predicted to be positive. Similarly, the case presented in Figure 1d – in which more able students allocate less time to total study effort – is not supported. Instead, to the extent that we are correcting fully for ability bias, the results indicate that absences have a negative causal effect on performance: this is consistent with the case presented in Figure 1b, with the implication that the number of classes offered is lower than the student’s optimising number. We note, however, that the quantile results for the endogenous model show that the significant negative effects of absence on performance hold only for upper quantiles. This is consistent with a combination of the cases depicted in Figures 1b and 1c, with more able students attending more classes than the less able (Figure 1c) and with this optimal number -for the more able only - being greater than the number provided (as in Figure 1b).

## **6. Concluding remarks**

There is now a significant body of work which attempts to delve inside the educational ‘black box’ in order to deepen the understanding of the processes by which human capital is acquired in learning environments. Much of this work has focused on the importance of factors such as class size and peer effects and has concentrated on educational attainment of pupils in compulsory schooling, with less attention paid to higher education. This is surprising given that there has been a growing policy focus on higher education, with governments in

many countries viewing the university sector as an important driver of research, development and growth. The nature of higher education is likely to be fundamentally different from compulsory primary and secondary education, with greater student autonomy in study in higher education. Our attention in the current paper has focused on the causal impact of class absence on student performance and on variations in the estimated effects according to particular student characteristics. The analysis has also incorporated a study of the determinants of class absence.

Our empirical analysis makes use of rich administrative panel for economics students at a UK university. We have exploited a number of key features of the data-set: (i) the panel nature of the data enables us to control for unobserved heterogeneity across students and hence for endogeneity between attendance and performance stemming from the likely influence of effort and ability on both; (ii) random assignment of students to classes avoids the potential endogeneity problems that occur when students can self select into classes; (iii) information on the time slots of the classes in the student's weekly timetable serves as a source of exogenous variation in a student's absence and hence yields potential instruments for the identification of a causal effect of absence on performance.

Our theoretical framework has outlined various possible links between absence and performance and how these might vary with student characteristics such as ability. The approach predicted that absence rates will be lower for more able students in the case in which ability is relatively highly correlated with the marginal productivity of class attendance rather than with other factors in the educational production function. We find empirical support for this prediction as, on average, absence is lower for students with better prior performance – a proxy for ability. In this same case, the model also predicted a negative relationship between absence and performance: both because of selectivity bias and because the marginal product of attendance is greater for more able students. The implications are

that: one should find a negative association between absence and performance; that this negative effect should be moderated when we correct for endogenous selection; and that the causal negative effect should be stronger for more able (and hence better-performing) students.

We have reported results consistent with each of these predictions, from which we conclude that a major driver of patterns in class attendance are differences in productivity of class attendance across students. In the absence of controls for unobserved heterogeneity, we find that there is a significant effect of class absence on the student's performance. This effect is weakened – though remains significant – when controlling for unobserved individual effects. We interpret this as consistent with the presence of ability bias in the naïve regression which fails to model the endogenous nature of absence and performance. In a quantile regression specification, it emerges that the adverse effect of missing class is greater for better-performing students, consistent with our hypothesis that effects are likely to vary with factors such as student ability.

What are the policy implications of our findings? We think that there are several. First, the evidence is consistent with the view that class attendance is a productive activity – the estimated causal effect of missing class is negative. Second, theory suggests that grade-maximising students might optimally choose to miss classes and hence that making classes compulsory could be inefficient. However, there is no evidence that missing class is associated with better performance, as would be implied in the model with compulsion and excess classes: compulsion does not seem to be creating problems – the administrative regime seems sufficiently flexible as to permit optimising choices by students. Third, the evidence suggests that class attendance is particularly productive for better-performing students: perhaps additional, voluntary classes could be organised with these students in mind. Alternatively, it might be appropriate to reflect on the nature of the teaching and

learning characteristics of classes with a view to enhancing their effectiveness for weaker students.

## **Appendix**

### **Bayesian estimate of the random effects**

$v_i$  is the unobserved individual specific random effects in the model (see equation (2)). Then,

$$f(v_i|data) = f(v_i|a_{i1}, a_{i2}, \dots, a_{im}) = f(a_{i1}, a_{i2}, \dots, a_{im}| v_i)f(v_i)/ f(a_{i1}, a_{i2}, \dots, a_{im})$$

Thus,

$$E(v_i | a_{i1}, \dots, a_{im}) = \int v_i f(v_i | a_{i1}, \dots, a_{im}) dv_i$$

$$= \frac{\int v_i f(a_{i1}, \dots, a_{im} | v_i) f(v_i) dv_i}{f(a_{i1}, \dots, a_{im})}$$

$f(a_{i1}, \dots, a_{im} | v_i)$  is the conditional likelihood and  $f(a_{i1}, \dots, a_{im})$  is the marginal likelihood which are obtained during the maximising of the likelihood function. The estimated  $E(v_i | a_{i1}, \dots, a_{im})$  is known as the Bayesian shrinkage estimator.

Notes: (1) Iv uses the predicted absences as instrument for the absence variable. (2) Absences is the proportion of missed tutorials. (3) The model also includes appropriate controls for another associated economics degree and the core courses in that degree. (4) \*\*\* significant at 1%, \*\* significant at 5%, \* significant at 10%.
